Abstract
This paper studies the impact of exchange rate movements on retail sector sales and prices in a small open economy. We develop a model with firm heterogeneity in importing and cross-border shopping among consumers. Exchange rate appreciations lower the cost of imported goods, but also lead to more cross-border shopping, hence the net impact on aggregate retail sales and prices is ambiguous. Using Canadian firm-level data from 2002–2012, we find empirical support for the theoretical foundations of the model. We then use the model and data to estimate the exchange rate elasticities of aggregate retail sales and prices. Our benchmark results indicate a small positive effect of exchange rate appreciations on sales, as the gains from lower-cost imports are slightly larger than the losses from greater cross-border shopping, and a deflationary effect of appreciations on retail prices. From 2002–2012, the Canadian exchange rate appreciated by 57%, which according to our model, led to a 6.5% reduction in the retail price index. We also find that the estimated elasticities of aggregate retail sales and prices grew by over this period, which was largely driven by import growth from China.

1 Introduction

Understanding the effect of exchange rate movements on prices and output is a central question in international economics. This paper studies the impact of exchange rate movements on retail sector prices and sales in a small open economy. We focus on quantifying the role of retail imports in transmitting exchange rate movements to aggregate outcomes in the sector.

To guide our empirical analysis, we develop a model with firm heterogeneity in productivity in the spirit of Melitz (2003), where retail firms can either import directly, or indirectly by purchasing imported goods from a domestic wholesale sector. An exchange rate appreciation disproportionately lowers the input costs of direct importers relative to other firms, and these lower costs are fully passed-through to prices, leading to higher sales. Meanwhile, appreciations also have a negative demand-side effect on the retail sector by lowering the price of foreign retail goods, which consumers can purchase by cross-border shopping. Our model gives rise to a closed-form expression for the exchange rate elasticity of aggregate retail sales, which is ambiguous in sign, capturing both the positive supply-side and negative demand-side effects. We also derive an expression for the exchange rate elasticity of the retail price index. The sign of this elasticity is also ambiguous. Exchange rate appreciations are deflationary due to pass-through of lower-cost imported goods to retail prices, but also inflationary, since greater cross-border shopping lowers the measure of domestic retail firms that operate, which raises the price index through a love-of-variety effect.

We then examine these issues empirically, beginning with a reduced-form regression analysis using Canadian firm-level data from the Annual Retail Trade Survey (ARTS), the Canadian Import Register (IR), and other administrative data for the years 2002–2012. We use these data to test several theoretical predictions of the model regarding the differential exchange-rate response of direct importing firms relative to other retailers. We find that a real exchange rate appreciation increases the sales of direct importing firms relative to other retailers. We also find that the difference in the sales-cost ratio between direct importing and other retailers is unaffected by exchange rate movements. These findings are consistent with the mechanism and market structure assumptions of the theoretical model. Direct importing firms experience cost shocks when the exchange rate appreciates, which are fully passed-through to lower retail prices, leading to higher sales relative to other firms. We also find, as other studies have,
that retailers in close proximity to the Canada-U.S. border experience lower sales due to exchange rate appreciations. This result is also consistent with mechanisms from the model, where exchange rate appreciations lead to greater spending on cross-border goods, which lowers sales for domestic retail firms. Overall, our firm-level reduced-form results provide empirical support for the theoretical framework we use in our subsequent model-based analysis.

Next, we quantify our model-derived equations for the exchange rate elasticities of aggregate retail sales and the retail price index for the years 2002–2012. We estimate several of the parameters needed to calculate these elasticities using a combination of firm and product-level data. In our benchmark specification, our results indicate that appreciations have a small positive effect on aggregate retail sales, as the negative effect of increased cross-border shopping is more than offset by the positive impact of lower-cost inputs through importing. With regards to exchange rate pass-through, we find that appreciations have a deflationary effect on retail prices. From 2002–2012, the Canadian exchange rate appreciated by 57%, which according to our model, led to a 6.5% reduction in the retail price index. We also find that the exchange rate elasticities of aggregate sales and the retail price index increased over this period, largely due to growth in Canadian retail imports from China. Overall, these results provide strong evidence that the import-cost channel is important for transmitting exchange rate movements to retail sales and prices in a small open economy.

Our findings contribute to several areas of literature. Numerous papers have examined the link between international trade and the retail sector. We contribute to this literature by developing a model that features retail firm heterogeneity, where firms have the option to import directly, or indirectly through a domestic wholesale sector, following a similar approach as in Ahn et al. (2011). The model gives rise to a premium, in terms of firm productivity and scale, associated with direct importing, which is consistent with both theoretical and empirical evidence from the existing literature. Unlike much of this literature, which focuses on the relationship between international trade and retail market structure, our analysis focuses on the relationship between exchange rate movements, importing, and retail firm performance.

1In many developed countries, the retail sector contributes a comparable share to GDP as the manufacturing sector, and the retail sector is highly dependent on imports of goods for resale. In 2012, the Canadian employment share of the retail sector was 11.8 percent as compared with 10 percent for the manufacturing sector (Statistics Canada Labour Force Survey, Statistics Canada table 14-10-0355). Despite this, the retail sector has received relatively little attention in this literature.

Direct importers are disproportionately exposed to exchange rate movements, and hence their sales are more sensitive to exchange rate movements than those of firms that do not import directly. This result is similar to evidence from Bernard et al. (2015), who find, using U.S. data, that exports to destinations with a high share of direct exports are more responsive to changes in the real exchange rate than are exports to markets served primarily by indirect exporters. We find that, as the Canadian dollar appreciated and import costs from China declined over the 2002–2012 period, the share of direct and indirect imports in retail sector sales grew significantly. As a result of this growth, the aggregate retail sales elasticity increased during this period.

Our findings also contribute to a large literature on exchange rate pass-through to consumer prices. Ours is among the first papers in this literature that explores the role of direct importing by the retail sector in determining pass-through, using firm-level data. We find no evidence that retailers that directly import adjust their sales-cost ratios, relative to other retailers, in response to exchange rate appreciations. This result is similar to findings in Goldberg and Hellerstein (2013), Gopinath et al. (2011), and Nakamura and Zerom (2010), which highlight that retailers largely adjust their prices to reflect changes in costs, and hence pass-through at the retailer level is high.3 Much of the existing literature focuses on documenting and explaining incomplete pass-through of exchange rate movements on account of the manufacturing and/or wholesale sector.4 In contrast, we emphasize that direct importing by retail firms leads to higher pass-through of exchange rate movements to consumer prices. As the costs of importing have declined over time (due to either decline in trade costs or exchange rate appreciation), retail firms increasingly enter into direct importing, and exchange rate pass-through increases. In our empirical results we find that, as the share of imports in retail sales rose over the 2002–2012 period, the exchange rate elasticity of the retail price index increased by 13%.

Finally, several papers have examined the impact of exchange rate movements on retail firm performance due to cross-border shopping, and particularly cross-border shopping between Canada and the

---

3Goldberg and Hellerstein (2013) find cost changes are largely passed through to prices based on retail-firm estimates for beer sold in Chicago. Gopinath et al. (2011) report similar findings based on estimates from a retail chain that operates in both the U.S. and Canada, as do Nakamura and Zerom (2010) based on estimates for the coffee industry. Gopinath and Itskhoki (2011) also highlight evidence that pass-through at the retail level is high, and consider the role of this and other empirical regularities in determining aggregate price adjustments.

4Examples of recent contributions to this literature include, Atkeson and Burstein (2008), Auer et al. (2018), Auer and Schoenle (2016), Berman et al. (2012), Corsetti et al. (2008), Devereux et al. (2017), Goldberg and Campa (2010), Goldberg and Hellerstein (2013), Burstein and Gopinath (2014), Gopinath et al. (2011), Hellerstein (2008), Nakamura and Zerom (2010), and Rodriguez-Lopez (2011).
We build a model where exchange rate appreciations lead to both lower retail sales due to greater cross-border shopping, as documented by this literature, and higher retail sales due to pass-through of lower-priced imports to retail prices. Ours is among the first studies to empirically document the importance of both the cross-border shopping channel and the import cost channel in determining the impact of exchange rate movements on retail-firm sales. Our model yields a closed-form expression for the exchange rate elasticity of aggregate retail sales that reflects this tension. Several of the earlier studies in this literature find that Canadian retail sales were negatively affected by appreciations, based on analysis of data from an earlier era. In contrast, our results indicate that the appreciation of the Canadian dollar from 2002–2012 had a positive effect on sales, due to the preponderance of imports in retail sales during this period. Further, we find the magnitude of this effect increased over time, largely as a result of growth in retail imports from China.

The rest of the paper proceeds as follows. In section 2, we present the model. In section 3, we describe our data and test several theoretical predictions of the model using a reduced-form analysis. In section 4, we estimate the model-derived exchange rate elasticities of aggregate retail sales and prices. In section 5, we conclude.

2 Model

This section develops a small-open-economy model that features retail firms that are heterogeneous in productivity and importing, and cross-border shopping among consumers. We model retail firms in the spirit of Melitz (2003), where we replace exporters from the original framework with importing retailers. Following the approach of Ahn et al. (2011), we include a wholesale sector in the model to

---

5 Studies including Baggs et al. (2018), Baggs et al. (2016), Campbell and Lapham (2004), Chandra et al. (2014), and Chen et al. (2017) find evidence of a significant effect of exchange rate shocks on retail firm performance as a result of cross-border shopping.

6 Some papers in the existing literature consider the role of imported goods, however none explore this channel using firm-level importing data. Baggs et al. (2018) and Baggs et al. (2016) both consider the role that cheaper imported products has in determining Canadian retail firm performance after currency appreciations but, due to data limitations, their analysis does not include direct firm-level evidence related to importing. Meanwhile, Devereux et al. (2017) report, based on data from the 2002–2006 period, that 92% of overall Canadian imported goods (in value terms) are invoiced in foreign currency. This suggests that a CAD appreciation should lower the cost of nearly all goods imported into Canada.

7 Kasahara and Lapham (2013) also develop a model with firm heterogeneity in productivity and importing. Their model considers the dual decision to import and export among firms, where imported inputs are combined with domestic inputs in a CES production function that exhibits productivity gains through “love of variety”. By comparison, our model entails less significant departures from the original Melitz (2003) model. This allows us to draw upon the well established theoretical results from Melitz (2003) in the model-based empirical analysis in this paper.
account for the fact that a large fraction of retail goods are imported indirectly by intermediaries.

Cross-border shopping is modeled by including a cross-border good as an additional (exogenously priced) product in households’ CES consumption bundle. We therefore abstract from the details of cross-border shopping that have been emphasized elsewhere in the literature. The simplicity of our model in this respect affords us the ability to derive closed-form analytical expressions for the exchange rate elasticities of aggregate retail sales and the retail price index.

2.1 Households

We consider an economy with a unit measure of households, each with 1 unit of labor and the following utility function:

\[
U = \left( \sum_{n=0}^{N} \frac{Q_n^{(\sigma-1)/\sigma} + Q_B^{(\sigma-1)/\sigma}}{\sigma/(\sigma-1)} \right),
\]

where \( Q_B \) is the quantity of the cross-border good consumed by households, and \( Q_n \) is the CES aggregate of varieties from country \( n \), adopting the convention that the domestic country is denoted as \( n = 0 \). The imported varieties from country \( n \in [1, N] \) include direct and indirect imported varieties. The parameter \( \sigma \) is the elasticity of substitution across varieties, and we make the standard assumption that \( \sigma > 1 \).

There is a single foreign firm that sells the cross-border good, \( Q_B \). Consumers cross-border shop by purchasing this good at an exogenous price, \( \tau_B \). This price, \( \tau_B \), includes the foreign price of the good converted into domestic currency, and any trade costs associated with cross-border shopping.

2.2 Retailers

All retailers are assumed to sell a domestic variety, which is produced using labor as the sole variable input. The cost of producing the domestic variety also entails a fixed operating cost \( f \). Retailers also have the option of selling imported varieties from up to \( N \) countries. Retailers produce imported varieties with a similar technology to the production function used for the domestic variety, however imported inputs are used instead of labor as the variable input. Retailers purchase imported inputs by one of two

\(^8\) We assume that the elasticity of substitution across varieties within each of the CES aggregates is also equal to \( \sigma \). \( Q_n = \left( \int_{\Omega_n} q_n(\omega)^{1/\sigma} \partial \omega \right)^{\sigma/(\sigma-1)} \).

\(^9\) Labor is the numeraire, and the nominal wage is normalized to unity.
means: direct importing or indirect importing. Direct importing entails the payment of a source country-specific variable cost, $\tau_n$, and fixed cost, $\eta_n$. Alternatively, retailers can purchase imported inputs from a perfectly competitive domestic wholesale sector at a source country-specific price $\tau_{wn} = (1 + a)\tau_n$, $a > 0$. Indirect importing via wholesalers also entails a country-specific fixed cost, $\eta_{wn} < \eta_n$. Thus, as in Ahn et al. (2011), indirect importing entails a higher variable cost and lower fixed cost relative to direct importing.

In producing retail goods (domestic or imported), retailers are heterogeneous in that output is proportional to their idiosyncratic productivity, $\phi$. We define $d_{wn}$ as an indicator variable that is 1 if a retailer indirectly imports from the wholesale sector, and 0 otherwise. The retail cost function for any source country-specific variety can then be fully summarized as follows:

$$c_n(\phi, d_{wn}) = \frac{(1 + d_{wn}a)\tau_n g_n(\phi, d_{wn})}{\phi} + (d_{wn}\eta_{wn} + (1 - d_{wn})\eta_n)f,$$

where $q_n(\phi, d_{wn})$ is the retailer’s source country-specific output function. For the domestic variety, the indirect import indicator variable is 0 by assumption, $d_{w0} = 0$, as it is produced with domestic labor. Therefore the variable cost of the domestic variety is equal to the nominal wage, which is normalized to 1, $\tau_0 = 1$. We also normalize the fixed cost of producing the domestic variety to 1, $\eta_0 = 1$. The productivity parameter $\phi$ is assumed to be drawn from a common continuous CDF, $G(\phi)$, with probability density function $g(\phi)$.

We assume that the retail market is characterized by monopolistic competition. Facing CES demand for their differentiated goods, retailers use the following pricing function to maximize profits:

$$p_n(\phi, d_{wn}) = (1 + d_{wn}a)\tau_n/(\rho\phi),$$

where $\rho \equiv (\sigma - 1)/\sigma$.

We now describe the endogenous firm-level productivity cutoffs that determine retailers’ operating and import status. The operating cut-off, $\phi_0$, is defined by the condition that a retailer with this productivity level makes zero profits from selling its domestic variety, $\pi_0(\phi_0, 0) = 0$. The indirect importing cut-off, $\phi_{wn}$, is defined such that a retailer of this type makes zero profits from indirectly importing from country $n$, $\pi_n(\phi_{wn}, 1) = 0$. Finally, the direct importing cut-off, $\phi_n$, is defined as the produc-

---

10Our assumption that retail firm markups are constant is consistent with existing evidence from the literature (see Gopinath and Itskhoki (2011)). It is also consistent with results from our empirical analysis in section 3, where we find that importing retail firms do not adjust their sales-cost ratio, relative to other firms, in response to exchange rate movements.
tivity level at which a retailer’s profits are equal across the two modes of importing from country \( n \), \( \pi_n(\varphi_n, 1) = \pi_n(\varphi_n, 0) \). The assumption that variable trade costs are lower for direct relative to indirect importing, \( \tau_n < \tau_n^w \), implies that the most productive firms will have higher profits from importing directly (i.e. firms with \( \varphi > \varphi_n \) import directly).\(^{11}\) As in Melitz (2003), the trade participation cut-offs, \( \varphi_n^w \) and \( \varphi_n \), can be expressed relative to the operating cut-off:

\[
\varphi_n^w = \varphi_0 \tau_n^w \eta_n^w \frac{1}{\sigma - 1}; \quad \varphi_n = \varphi_0 \left( \frac{\eta_n - \eta_n^w}{\tau_n^{1-\sigma} - \tau_n^w 1-\sigma} \right)^{\frac{1}{\sigma - 1}}.
\] (1)

Combining the cut-off equations in (1) with the CES demand and pricing functions, we can write the profit functions as follows:

\[
\pi_n(\varphi, d_n^w) = f \left( \frac{\varphi}{\varphi_0} \right)^{\sigma-1} \left( (1 + d_n^w a) \tau_n \right)^{1-\sigma} - d_n^w \eta_n - (1 - d_n^w) \eta_n
\]

Next, we solve for mean retail profits, \( \tilde{\pi} \):\(^{12}\)

\[
\tilde{\pi} = \int_{\varphi_0}^{\infty} \pi_n(\varphi, 0) \frac{g(\varphi)}{1 - G(\varphi_0)} \partial \varphi + \sum_{n=1}^{N} \left( \int_{\varphi_n}^{\varphi_n^w} \pi_n(\varphi, 1) \frac{g(\varphi)}{1 - G(\varphi_0)} \partial \varphi + \int_{\varphi_n^w}^{\infty} \pi_n(\varphi, 0) \frac{g(\varphi)}{1 - G(\varphi_0)} \partial \varphi \right)
\]

\[
= f k(\varphi_0) + \sum_{n=1}^{N} \left( \frac{1 - G(\varphi_n^w)}{1 - G(\varphi_0)} \eta_n^w f k(\varphi_n^w) + \frac{1 - G(\varphi_n)}{1 - G(\varphi_0)} (\eta_n - \eta_n^w) f k(\varphi_n) \right), \quad (2)
\]

where \( k(\varphi) \equiv \left( \frac{\tilde{\phi}(\varphi)}{\varphi} \right)^{\sigma-1} - 1 \), and \( \tilde{\phi}(\varphi) = \left( \frac{1}{1 - G(\varphi_0)} \int_{\varphi}^{\infty} \xi^{\sigma-1} g(\xi) \partial \xi \right)^{1/(\sigma-1)} \).

We assume that retail firms must pay a fixed cost to enter the industry, \( f_e \), which implies the free-entry condition: \( \tilde{\pi} = f_e (1 - G(\varphi_0))^{-1} \). The unique equilibrium value of \( \varphi_0 \) is determined by combining this free-entry condition with equation (2).

\(^{11}\)Our assumptions regarding the trade cost parameters are sufficiently weak to allow for a variety of different outcomes with regard to indirect importing. For example, if the fixed cost of indirect importing is sufficiently low, then all operating firms will import either via wholesalers or through direct importing. Conversely, if the fixed cost of indirect importing is exorbitantly higher, then wholesalers may be by-passed completely, with all imported inputs being imported directly.

\(^{12}\)Detailed derivations of the trade participation cutoffs, the firm-level profit function, and the mean retail profits are provided in sections 2.1, 2.2, and 2.3 of the online appendix, respectively.
2.3 Aggregate Retail Sales and Retail Price Index

In this section we derive analytical expressions for aggregate retail sales and the retail price index, which are the key equations that are used in the model-based empirical analysis of this paper.

The household budget constraint requires that total income equals aggregate expenditures on the sum of retail and cross-border goods, \( 1 = PQ + P_BQ_B \). Note that the structure of CES demand is such that the ratio of expenditures on the cross-border good relative to those on any other variety can be written as:

\[
\frac{P_BQ_B}{P_0(\varphi, 0)q_0(\varphi, 0)} = \left( \frac{\tau_B}{p_n(\varphi, d^n)} \right)^{1-\sigma}
\]

In particular, the ratio of expenditures on the cross-border good relative to expenditures on a domestic variety produced by a retailer with cut-off productivity \( \varphi_0 \), is:

\[
P_BQ_B = \left( \frac{\tau_B}{p_0(\varphi, 0)} \right)^{1-\sigma} \Rightarrow P_BQ_B = (\tau_B \rho \varphi_0)^{1-\sigma} p_0(\varphi, 0)q_0(\varphi, 0) \quad (3)
\]

Recall that the operating cut-off, \( \varphi_0 \), is defined by the zero-profit condition \( \pi_0(\varphi_0, 0) = 0 \). This zero-profit condition implies the following sales equation for a retailer with cut-off productivity: \( p_0(\varphi, 0)q_0(\varphi, 0) = \sigma f \). Combining this expression with equation (3) and the household budget constraint, yields:

\[
PQ = 1 - P_BQ_B = 1 - (\rho_0 \varphi_0)^{1-\sigma} \sigma f,
\]

which is our analytical expression for aggregate retail sales.

We define \( \bar{P} \) as the aggregate price index, \( \bar{P} = (P^{1-\sigma} + \tau_B^{1-\sigma})^{1/(1-\sigma)} \). That is, the aggregate price index is a CES aggregate of the retail price index, \( P \), and the price of the cross-border good, \( \tau_B \). Re-arranging the aggregate price index yields the following equation for the retail price index:

\[
P = (\bar{P}^{1-\sigma} - \tau_B^{1-\sigma})^{1/(1-\sigma)} \quad (5)
\]

In the next section, we use equations (4) and (5) to derive a analytical expressions for the exchange rate elasticities of aggregate retail sales and the price index.
2.4 Exchange Rate Elasticities of Aggregate Retail Sales and the Retail Price Index

In this section we derive analytical expressions for the exchange rate elasticities of aggregate retail sales and the price index. We denote the nominal exchange rate by $E$, where an increase in $E$ indicates an appreciation in the domestic currency. We assume that imports from every country are denoted in a common foreign currency, and $E$ denotes the units of this foreign currency that can be exchanged for one unit of the domestic currency. As a small open economy, we assume that the domestic country takes $E$ as exogenous. An appreciation is assumed to have the effect of decreasing the variable cost of importing from any foreign country, $\partial \tau_n / \partial E < 0$, for all $n \in [1, N]$, and decreasing the cost of cross-border shopping, $\partial \tau_B / \partial E < 0$.\(^{13}\) Throughout this section, we define all elasticities using the following notation $\varepsilon_{yx} = \partial \ln (y) / \partial \ln (x)$. Starting from equation (4), the elasticity of aggregate retail sales with respect to percentage change in the exchange rate is:

$$\varepsilon_{PQ} E = (\sigma - 1) \frac{P_B Q_B}{P Q} (\varepsilon_{E}^{\phi_0} - |\varepsilon_{E}^{\tau_B}|), \quad (6)$$

We next focus on deriving a representation for the exchange rate elasticity of the operating cut-off, $\varepsilon_{E}^{\phi_0}$, that can be estimated using firm and product-level data. It is relatively straightforward to estimate the remaining variables in equation (6), as is discussed in detail in section 4.1.

To derive an analytical expression for $\varepsilon_{E}^{\phi_0}$, we begin by noting that the free-entry condition can be written $\hat{\pi}(1 - G(\varphi_0)) = f_e$. Equating this representation of the free-entry to equation (2), multiplied through by $1 - G(\varphi_0)$, yields:

$$f_e = f(1 - G(\varphi_0))k(\varphi_0) + \sum_{n=1}^{N} (\eta_n^{w}f(1 - G(\varphi_n^{w}))k(\varphi_n^{w}) + (\eta_n - \eta_n^{w})f(1 - G(\varphi_n))k(\varphi_n)) \quad (7)$$

Next we differentiate both sides of equation (7) with respect to the exchange rate, $E$, and re-arrange to

---

\(^{13}\)In our setting, the $\tau_B$ represents the price of the cross-border good from the perspective of domestic consumers. When the domestic currency appreciates, this price declines since foreign retail goods are priced in foreign currency. In section 4.1 we empirically validate our assumptions that variable import trade costs and the cost of cross-border good are decreasing with respect to the exchange rate.
derive the following equation for the elasticity $\varepsilon_{E}^{\varphi_{0}}$:\textsuperscript{14}

$$\varepsilon_{E}^{\varphi_{0}} = \frac{\sum_{n=1}^{N} \left( \eta_{n}^{w}(k(\varphi_{n}) + 1)(1 - G(\varphi_{n}))|\varepsilon_{n}^{\tau_{n}}| + (\eta_{n} - \eta_{n}^{w})(k(\varphi_{n}) + 1)(1 - G(\varphi_{n}))|\varepsilon_{n}^{\tau_{n}}| \right) \left( k(\varphi_{0}) + 1 \right)(1 - G(\varphi_{0}))}{\sum_{n=1}^{N} \left( \eta_{n}^{w}(k(\varphi_{n}) + 1)(1 - G(\varphi_{n})) + (\eta_{n} - \eta_{n}^{w})(k(\varphi_{n}) + 1)(1 - G(\varphi_{n})) \right)}.$$  

That is, the elasticity $\varepsilon_{E}^{\varphi_{0}}$ is equal to the weighted import trade cost elasticity, where the weights are given by the import share of retail sales for each respective source country. Note that the numerator of the source country-specific import shares, $P_{n}Q_{n}$, is inclusive of sales generated from directly and indirectly imported varieties.\textsuperscript{15} Substituting equation (8) into equation (6) yields:

$$\varepsilon_{E}^{PQ} = (\sigma - 1) \frac{P_{B}Q_{B}}{P_{B}Q_{B}} \left( \sum_{n=1}^{N} \left( |\varepsilon_{n}^{\tau_{n}}| \frac{P_{n}Q_{n}}{PQ} - |\varepsilon_{n}^{\tau_{B}}| \right) \right),$$  

(9)

The tension between the supply and demand-side effects of an appreciation are captured in the elasticity in equation (9). The benefits of an appreciation for retail-sector sales result from a decline in import trade costs, $\varepsilon_{E}^{\tau_{n}} < 0$. This supply-side effect is larger if import trade costs are highly sensitive to changes in the exchange rate (i.e. if the magnitude of $\varepsilon_{E}^{\tau_{n}}$ is large), and if the import share of sales is high. The negative effect of an appreciation for retail-sector sales results from a decline in the cross-border shopping cost, $\varepsilon_{E}^{\tau_{B}} < 0$. This demand-side effect is larger if the cost of cross-border shopping is highly sensitive to changes in the exchange rate (i.e. if the magnitude of $\varepsilon_{E}^{\tau_{B}}$ is large).

We now derive an analytical expression for the exchange rate elasticity of the retail price index. Starting from equation (5), the elasticity of the retail price index is:

$$\varepsilon_{E}^{P} = - \left( \frac{\bar{P}}{P} \right)^{1-\sigma} |\varepsilon_{E}^{\varphi_{0}}| + \left( \frac{\bar{\tau}_{B}}{\bar{P}} \right)^{1-\sigma} |\varepsilon_{E}^{\tau_{B}}|,$$  

(10)

where make use of the result that $\varepsilon_{E}^{P} = -\varepsilon_{E}^{\varphi_{0}}$, which follows from the fact that $\bar{P} = (\sigma f)^{1/(\sigma - 1)}/(\rho \varphi_{0})$.

\textsuperscript{14}A detailed derivation of the elasticity of the operating cutoff with respect to the exchange rate is provided in section 2.4 of the online appendix.

\textsuperscript{15}By country-specific “import shares”, we specifically mean the ratio of sales of (directly and indirectly) import goods from country $n$ relative to total retail sales.
as derived in appendix 6.1. Next, making use of the definition of $P$, and the representation of $\varepsilon_{E}^{\tau_0}$ from equation (8), we can rewrite the equation (10) as:

$$
\varepsilon_{E}^{P} = -\frac{1}{1 - (P/\tau_B)^{\sigma-1}} \sum_{n=1}^{N} \left| \varepsilon_{E}^{\tau_n} \right| \frac{P_n Q_n}{P Q} + \frac{(\bar{P}/\tau_B)^{\sigma-1}}{1 - (P/\tau_B)^{\sigma-1}} |\varepsilon_{E}^{\bar{\tau}}| \tag{11}
$$

Finally, we note that, as a consequence of CES demand, $P_B Q_B = \bar{P} \bar{Q} (\bar{P}/\tau_B)^{\sigma-1}$. Making use of this expression and the fact that $\bar{P} \bar{Q} = PQ + P_B Q_B$, we rewrite equation (11) as:

$$
\varepsilon_{E}^{P} = -\frac{\bar{P} \bar{Q}}{P Q} \sum_{n=1}^{N} \left| \varepsilon_{E}^{\tau_n} \right| \frac{P_n Q_n}{P Q} + \frac{P_B Q_B}{P Q} |\varepsilon_{E}^{\tau_B}| \tag{12}
$$

where $\bar{P} \bar{Q}/(PQ)$ is the ratio of total expenditures (inclusive of retail and cross-border expenditures) relative to retail expenditures. Equation (12) captures the effect on an appreciation on the retail price index in an intuitive way. An appreciation reduces import trade costs, $\varepsilon_{E}^{\tau_n} < 0$, which lowers the price of imported varieties and this puts downward pressure on the retail price index. This supply-side effect is larger when the exchange rate elasticity of variable import trade costs is high; when the import share of sales is high; and when the share of domestic retail in total expenditures is high. In contrast, an appreciation lowers the cost of cross-border shopping, $\varepsilon_{E}^{\tau_B} < 0$, and this puts upward pressure on the retail price index. The decline in the cost of cross-border shopping increases demand for the cross-border good, and this has a negative effect on the total measure of retail varieties.\footnote{Interestingly, changes in cross-border trade costs only affect the retail price index through influencing the total measure of varieties. The operating and trade participation cut-offs are unaffected by changes in $\tau_B$, since these equilibrium cutoffs depend only on the retail supply-side parameters of the model. This can be seen from the trade participation cutoff equations in (1), and from the equations that determine the operating cutoff (equation (7) and the free-entry condition).}

Under CES demand, a reduction in the measure of varieties results in an increase in the retail price index. This inflationary demand-side effect is larger when the exchange rate elasticity of cross-border costs is high, and when the share of cross-border spending in total retail spending is high. To summarize, changes in the exchange rate may either decrease or increase the retail price index depending on the relative magnitudes of the supply and demand-side effects respectively.

The theoretical ambiguity of the sign of the effect of an appreciation on aggregate retail sales and the retail price index motivates our model-based analysis in section 4. In that section we discuss how each of the variables in the elasticity equations for aggregate retail sales and the retail price index, equations

12
(9) and (12) respectively, can be estimated from a combination of firm-level and product-level data.

2.5 Theoretical Firm-Level Predictions

Our theoretical framework has implications for how a retail firm’s sales and prices respond to the exchange rate movements. In this section we derive two theoretical predictions that we subsequently test with firm-level data in section 3.

Our first theoretical prediction relates to the impact of an exchange rate movement on retail firm-level sales. Formally, we make the following proposition:

Proposition 1: Consider a retailer that sells imported varieties from \( N' \leq N \) countries. The exchange rate elasticity of the retailer’s sales will be higher if it imports directly, rather than indirectly, from all \( N' \) countries.

Proof: The logarithm of retail firm-level total sales, including sales of domestic and imported varieties, is given by the equation:

\[
\log (p(\varphi)q(\varphi)) = \log \left( \sigma f \left( \frac{\varphi}{\varphi_0} \right)^{\sigma - 1} \left( 1 + \sum_{n=1}^{N'} (1 + d_w a)^{1-\sigma} \tau_n^{1-\sigma} \right) \right)
\]  

Differentiating equation (13) with respect to the logarithm of the exchange rate yields the following retail firm-level sales elasticity equation:

\[
\varepsilon_{pq}^{E} = (1 - \sigma)\varepsilon_{0}^{E} + (\sigma - 1) \frac{\sum_{n=1}^{N'} (1 + d_w a)^{1-\sigma} \tau_n^{1-\sigma} |\varepsilon_n^{E}|}{1 + \sum_{n=1}^{N'} (1 + d_w a)^{1-\sigma} \tau_n^{1-\sigma}}
\]  

We define \( \varepsilon_{pq}^{E} | d_w = 0 \) and \( \varepsilon_{pq}^{E} | d_w = 1 \) as the retail firm-level sales elasticity for a direct and indirect importer, respectively. Proposition 1 implies that \( \varepsilon_{pq}^{E} | d_w = 0 > \varepsilon_{pq}^{E} | d_w = 1 \), the proof of which follows directly from equation (14):

\[
\varepsilon_{pq}^{E} | d_w = 0 > \varepsilon_{pq}^{E} | d_w = 1 \iff \frac{\sum_{n=1}^{N'} \tau_n^{1-\sigma} |\varepsilon_n^{E}|}{1 + \sum_{n=1}^{N'} \tau_n^{1-\sigma}} > \frac{(1 + a)^{1-\sigma} \sum_{n=1}^{N'} \tau_n^{1-\sigma} |\varepsilon_n^{E}|}{1 + \sum_{n=1}^{N'} (1 + a)^{1-\sigma} \tau_n^{1-\sigma}}
\]

\[
\iff 1 + \sum_{n=1}^{N'} (1 + a)^{1-\sigma} \tau_n^{1-\sigma} > (1 + a)^{1-\sigma} + \sum_{n=1}^{N'} (1 + a)^{1-\sigma} \tau_n^{1-\sigma} \iff 1 > (1 + a)^{1-\sigma}
\]
where the finally inequality holds under the assumptions that $a > 1$ and $\sigma > 1$.

The intuition for this result is as follows. Direct importers pay a lower variable cost for imports relative to indirect importers. As a result, imports make up a larger fraction of the sales of direct importers, and therefore they have a higher elasticity of sales with respect to the exchange rate as compared with indirect importers. In section 3 we test the theoretical prediction in Proposition 1 by estimating the exchange-rate elasticity of sales for direct importers relative to other firms.

Our second proposition pertains to the response of firm-level prices to exchange rate variation. Ideally, we would state our model’s prediction of the exchange rate-elasticity of firm-level prices, and test this hypothesis with firm-level data. Unfortunately unit prices are not available in our data, so we instead frame our second proposition in terms of the sales-cost ratio. As we establish below, the CES demand structure and monopolistically competitive market structure assumptions in our model have implications for the sales-cost ratio. This allows us to use firm-level data on the sales-cost ratio in section 3 to test the hypothesis that follows from our assumptions regarding the market structure in our model.

Prior to stating our second proposition, it is important to formalize the concept of the sales-cost ratio from a theoretical perspective. We define the sales-cost ratio as:

\[
\nu(\varphi, d^w_n) = \frac{\sum_{n=0}^{N} p(\varphi, d^w_n) q(\varphi, d^w_n)}{\sum_{n=0}^{N} (1 + d^w_n a) \tau_n q(\varphi, d^w_n)} = \frac{\sum_{n=0}^{N} p(\varphi, d^w_n) q(\varphi, d^w_n)}{\sum_{n=0}^{N} cogs(\varphi, d^w_n)}
\]  

(15)

That is, the sales-cost ratio is the ratio of total sales to the total cost of good sold ($cogs$). We conceptualize $cogs$ as costs that are paid by the retailer to purchase the goods that it sells. Importantly, our definition of $cogs$ does not incorporate the firm’s productivity parameter, which we think of as affecting the firms output after the goods enter the firm’s possession. For example, firm-level productivity in our retail setting may be thought of as the idiosyncratic quality of the shopping experience that is provided by the retailer.

Having defined the sales-cost ratio, we state our second proposition as follows:

**Proposition 2:** A firm’s sales-cost ratio only depends on its firm-level productivity and the CES mark-up, and therefore is unaffected by exchange rate movements or its import status.

**Proof:** The result follows immediately by multiplying the numerator and denominator of equation (15) by $\varphi \rho$, and from the definition of the firm’s monopolistically competitive price, which together
imply \( \nu(\varphi, d^n_w) = \nu(\varphi) = 1/\varphi\). \hfill \Box

Intuitively, the higher a firm’s CES mark-up, \(1/\rho = \sigma/(\sigma - 1)\), the higher its price and its sales-cost ratio, whereas higher a firm’s productivity, \(\varphi\), the lower its price and its sales-cost ratio. Proposition 2 implies that the exchange-rate elasticity of the firm-level sales-cost ratio is zero, and that the sales-cost ratio is unaffected by import status after controlling for firm-level productivity.

To summarize, the model developed in this section augments the canonical Melitz (2003) model by integrating retail firm heterogeneity, importing, and cross-border shopping among consumers in a simple and concise way. From this framework, we derived closed-form analytical expressions for the exchange rate elasticities of aggregate retail sales and the price index (equations (9) and (12), respectively). Both of these equations intuitively depend on the share of imported goods in domestic retail sales: as this share increases, exchange rates movements have more positive (negative) effect on aggregate retail sales (the retail price index). In section 4, we derive estimates of the share of imported goods in domestic retail sales from product and firm-level data, and show that import growth from China has pushed up these shares throughout the 2002–2012 period. We also derive all other parameters required to compute equations (9) and (12), which permits us to quantify both elasticities for Canada throughout 2002–2012. Prior to estimating these elasticities, we first look to provide empirical support for several important micro-foundations of our model and the theoretical predictions derived in this sub-section, using firm-level data.

3 Data and Reduced-Form Analysis

In this section we introduce the firm-level data that is used throughout our empirical analysis. We also use reduced-form regression analysis to provide empirical support for the foundations of our theoretical framework, including testing the two theoretical firm-level predictions that were derived in section 2.5.

Our empirical analysis uses micro data from the Canadian Annual Retail Trade Survey (ARTS) merged with firm-level import data derived from Statistics Canada’s Import Register (IR). Data from the ARTS are used for the two outcome variables of interest in our reduced-form analysis, firm-level sales and the sales-cost ratio, denoted \(p_{i,t}q_{i,t}\) and \(\nu_{i,t}\) respectively.\(^{17}\) We compute the sales-cost ratio by

\(^{17}\)In the case where a firm operates in multiple retail NAICS 4-digit industries, the ARTS requires that the firm complete separate surveys for each of its respective industries. For the sales variable, the data is even further disaggregated,
dividing sales by the cost of goods sold (cogs), \( \nu_{i,t} = pq_{i,t}/cogs_{i,t} \), where \( cogs_{i,t} \) are the cost of goods sold of firm \( i \) in year \( t \). The cost of goods sold, \( cogs_{i,t} \), is defined implicitly in the ARTS by the following inventory accounting formula: \( \Delta \text{inventories}_{i,t} = purchases_{i,t} - cogs_{i,t} \), where \( purchases_{i,t} \) is the cost of new purchases and \( \Delta \text{inventories}_{i,t} \) is the difference between closing and opening inventories.\(^{18}\)

The sales-cost ratio corresponds closely to the “gross margin”, which is a commonly used measure of firm profitability.\(^{19}\)

Our objective is to test our theoretical predictions regarding the effect of changes in the Canada-U.S. real exchange rate on firm-level sales, and the sales-cost ratio. We define the real exchange rate as \( RER_{j,t} = E_{USD/CAD,t}P_{j,CAN,t}/P_{j,US,t} \), such that an increase in \( RER_{j,t} \) reflects a real appreciation in Canadian retail sector \( j \). In calculating the real exchange rate, we use data from Statistics Canada for the nominal exchange rate, \( E_{USD/CAD,t} \), and the Canada-U.S. NAICS 4-specific relative CPI, \( P_{j,CAN,t}/P_{j,US,t} \). We define an indicator variable for import status, \( 1(Importer_{i,t}) \), that takes a value of one if an firm had a positive value of imports in the IR. We acknowledge many retailers do not directly import, yet nevertheless sell products that are imported by an intermediary. Thus our import indicator variable distinguishes direct-importing retailers from other firms that may or may not import indirectly.

Figure 1 reports how the Canada-U.S. exchange rate varied between 2002 and 2012. There are two important takeaways from this figure. The first is that annual fluctuations in exchange rate were strongly correlated with oil price fluctuations throughout our period of study, and hence can be interpreted as exogenous from the perspective of retail firms in a small open economy like Canada. The second is that the Canadian dollar appreciated significantly over the course of 2002–2012, which likely had an impact on both firm and consumer decisions regarding the purchase of goods prices in U.S. dollars.

For our reduced-form empirical analysis, we adapt the standard trade premium regression framework as firms are required to report their sales at each of their store locations. To match the level of aggregation in our import data, we aggregate the ARTS data to the firm-level. In aggregating variables to the firm level, we define a firm’s 4-digit NAICS classification according to the sector in which the firms has the largest fraction of its sales. All nominal firm-level values in this paper are converted to real values using NAICS 4-digit CPI deflators. Throughout this paper, our use of the term “firm” corresponds with Statistics Canada’s definition of an enterprise.

\(^{18}\)We censor our data by excluding all non-positive values for sales and cost of goods sold. For our \( \nu_{i,t} \) regressions, we also exclude outlier observations for the sales-cost ratio, defined as cases where the ratio is greater than 5. This exclusion results in our dropping less than one percent of the firm-level observations in our sample.

\(^{19}\)Specifically, the “gross margin” is commonly defined as \( \text{gross margin}_{i,t} = (sales_{i,t} - cogs_{i,t})/sales_{i,t} \); hence, our measure is related such that \( \nu_{i,t} = 1/(1 - \text{gross margin}_{i,t}) \).
that is commonly used in the empirical trade literature, as follows:

\[ y_{i,j,t} = \beta_0 + \beta_1 \ln(RER_{j,t}) + (\beta_2 + \beta_3 \ln(RER_{j,t})) 1(Import_{i,t}) + (\beta_4 + \beta_5 \ln(RER_{j,t})) \ln(dist_{i,t}) \]

\[ + \beta_6 \ln(HHCons_{j,t}) + Z_t \gamma + \beta_7 t + \delta_j + u_{i,j,t}, \]  

where the dependent variable, \( y_{i,j,t} \), is either the logarithm of sales or the logarithm of the sales-cost ratio. The key variables of interest are log real exchange rate, \( \ln(RER_{j,t}) \), the import indicator, \( 1(Import_{i,t}) \), and the interaction between these two variables.

Regression equation (16) also includes a distance variable, \( \ln(dist_{i,t}) \), that accounts for proximity to the U.S. border.\(^{20}\) We center the \( \ln(dist_{i,t}) \) variable to have a mean zero, so that the regression coefficients can be interpreted as marginal effects for a firm that is located at the average log distance from the U.S. border. We also include an interaction of this distance variable with the with real exchange rate variable, \( \ln(RER_{j,t}) \). The inclusion of the distance variable is motivated by research by Baggs et al. (2016), who show that Canadian retailer sales are negatively affected by real exchange rate appreciations, and that this effect is attenuated with distance to the U.S. border. Baggs et al. (2016) attribute this result to cross-border shopping to the U.S. by Canadian consumers, which increases when the Canadian dollar appreciates, reducing demand at Canadian retail stores.

The matrix \( Z_t \) contains a set of aggregate control variables that might also affect retail sales. These aggregate controls variables include: a measure of annual household consumption in each NAICS 4 industry \( j \), \( \ln(HHCons_{j,t}) \),\(^{21}\) the General Sales Tax rate, \( GST_t \), the logarithm of real median household income, \( \ln(Inc_t) \), and the real interest rate \( RIR_t \).\(^{22}\) The regression specification also includes a variable \( t \) to allow for a trend in the dependent variable reflecting other dynamic factors that are not controlled for by the other regressors. Finally, we include a dummy variable for each NAICS 4-digit industry to control for any time-invariant sector-specific factors that may affect our dependent variables at the industry level.

\(^{20}\)This variable is calculated in three steps. First, we calculate the euclidean distance to the U.S. border from each retail store in ARTS. We approximate the location of each store using the centroid of its forward sorting area (a forward sorting area (FSA) is the geographic area defined by the first 3 digits of the stores postal code - there are 1,620 FSAs in Canada). Second, we calculate each store’s share of its parent firm’s total sales. Using the store specific distances from step one, and the shares from step two as weights, the third step is to calculate the weighted average distance to the U.S. border for each firm-level observation in the sample.

\(^{21}\)Data for the household consumption variable is sourced from Statistics Canada.

\(^{22}\)Data for these variables are sourced from the Canadian Revenue Agency, Statistics Canada, and the World Bank respectively. All control variables are annual.
Summary statistics for the variables included in our regression analysis are reported in Table 1. On average, annual firm-level retail sales are almost 45 million CAD in our data; standard deviation in retail sales is over 9 times this figure, which indicates significant heterogeneity in retail firm size and motivates our theoretical approach in section 2. The average sales-cost ratio among firms in our data is roughly 1.5, and this dispersion of this ratio is low as the coefficient of variation is 34%.

3.1 Reduced-form Results: OLS, FE, and PSM

We estimate regression equation (16) by ordinary least squares (OLS), fixed effects (FE), and propensity score matching (PSM) estimation, with standard errors clustered at the firm level. Our goal is to estimate the impact of exchange rate movements on retail firm sales and sales-cost ratios. Results are reported in Table 2. The OLS regressions in columns 1 and 4 control for various observable characteristics that might influence firm sales. The FE regressions in columns 2 and 5 additionally control for any time-invariant unobserved heterogeneity at the firm level. The PSM regressions in columns 3 and 6 attempt to identify the causal effect by matching each importer in our sample with a control firm that doesn’t import directly but has a statistically similar propensity to import based on observable characteristics.23 The two dependent variables, ln(pq_{i,t}) and ν_{i,t}, correspond to the logarithm of sales and the sales-cost

23The PSM technique applied here follows a similar approach taken by Meinen and Raff (2018) and others. Details of how we implement this technique are described in the Appendix.
ratio measure described above.

Standard errors are clustered at the firm-level. All specifications include a full set of NAICS 4-digit dummy variables. *** p<0.01, ** p<0.05, * p<0.1. The reduction in the sample size between the OLS/FE and PSM specifications reflects the fact that the PSM estimator uses only the matched sample of direct importing firms. For each estimator (OLS, FE, and PSM), the sample size for the sales-cost ratio, \nu_{i,t}, is slightly smaller than the log sales outcome variable, ln(pq_{i,t}), as the variable \nu_{i,t} is censored to exclude firms with a sales-cost ratio greater than 5.

We first discuss results related to non-direct-importing firms, since these results apply most directly to the existing literature. In column 1, which reports results with log sales as the dependent variable, the coefficient on the variable real exchange rate variable is negative but statistically insignificant; in column 2, this coefficient is negative and highly significant; and in column 3, this coefficient is, like in column 1, negative but statistically insignificant. These results suggest that the sales of a non-direct-importing retailer at average log distance from the U.S. border are either neutral or negatively affected by a real appreciation. According to columns 1 and 2, any negative effect of appreciations on sales is attenuated with distance from the U.S. border, as the interaction between the distance variable and the real exchange rate is positive and highly significant. These results are consistent with evidence from Baggs.
et al. (2016), who argue that Canadian retail firms face a loss in demand due to cross-border shopping during periods of appreciation in the CAD. Meanwhile, the coefficient estimate for this parameter under the PSM specification in column 3 is statistically insignificant.

In column 4–6, which reports results with the sales-cost ratio as the dependent variable, the coefficient on the real exchange rate variable is negative and statistically significant in the OLS specification, but not statistically different from zero in FE or PSM specifications. Thus, our FE and PSM results are consistent with our second theoretical proposition, in that it indicates that non-direct-importing retail firms did not adjust their sales-cost ratios when exchange rate appreciated over the 2002–2012 period.

Next, we discuss results related to direct importing firms. In column 1, the estimated coefficient for the import indicator variable, 1(*Importer*$_{i,t}$), is positive and highly significant under OLS, which may be attributed to either large/growing firms self-selecting into importing, or to a causal effect of importing on sales. Both of these channels are found to be significant in previous studies that examine importing firms. In column 2, which reports results with firm-level fixed effects, the estimated coefficient for the import indicator variable is also positive and significant, although it less than one fifth the magnitude of the coefficient in column 1. This difference suggests that the OLS estimate is influenced by selection bias due to unobserved time-invariant firm-level attributes, which are controlled for with firm-level fixed effects. In column 3, the estimated coefficient for the import indicator variable is positive and highly significant. This indicates that direct importing by retailers leads to higher sales.

A more novel finding in columns 1–3 is the positive and significant coefficients on the interaction between the import indicator and the real exchange rate. This result is consistent with our first theoretical proposition, as it suggests that Canadian retailers that are direct importers fare better than other firms during an appreciation. The estimated coefficients on the interaction term in OLS and FE specifications are very similar, suggesting that the bias associated with unobserved firm-level attributes is not a large issue for this coefficient estimate. In fact, our PSM results in column 3, which can be most closely aligned with causality, suggest a larger positive impact of an exchange rate appreciations on importer sales relative to the results in columns 1 and 2. Together, these results indicate that the exchange rate appreciations of the CAD during the period 2002–2012 led to higher sales for direct importing firms relative to other retailers. These results are intuitive, since a real appreciation acts as a supply shock.

24 For examples of studies that provide evidence of both these channels, see Amiti and Konings (2007), Halpern et al. (2015), Kasahara and Lapham (2013), and Kasahara and Rodrigue (2008).
that lowers costs for importing retailers, which can then be passed on to lower retail prices, induce expenditure switching among consumers, and yield higher sales relative to non-importers. Of course, such a transmission might not take place if retail firms raise their sales-cost ratios and offset the fall in import prices, a possibility we examine in columns 4–6.

In column 4, the import indicator variable has a positive and statistically significant relationship with the sales-cost ratio, whereas the corresponding coefficients in columns 5 and 6 are insignificant. The former OLS estimate could reflect self-selection of more profitable firms into importing. The latter results indicates that, once self-selection into importing is accounted for, there is no evidence that firms that enter into importing raise their sales-cost ratios. The lack of a statistically significant effect on sales-cost ratio for the FE and PSM specifications is consistent with proposition 2.

For the interaction between the import indicator and the real exchange rate, the coefficient is statistically insignificant in columns 4–6. Hence we find no evidence that direct importing retail firms adjust their sales-cost ratios, relative to other firms, in response to exchange rate appreciations. This is also consistent with proposition 2, and provides support for the exchange rate transmission mechanism in our model. That is, an exchange rate appreciation lowers the intermediate input costs for direct importing retailers, who do not adjust their sales-cost ratios, and hence pass-through these lower costs to lower prices, inducing greater sales relative to other retailers.

The remaining coefficients estimates in table 2 are broadly consistent with economic intuition and previous research. We omit a detailed discussion of these results, as our primary motivation is to test the theoretical predictions and assumptions of our model by focusing on the relationships between the outcomes and key variables of interest in our regression results.

All together, our results in Table 2 provide evidence of several key relationships that are relied upon in our model-based analysis. We find evidence that sales of firms that import directly are more sensitive to exchange rate movements than sales of firms that do not, ceteris paribus, which is consistent with Proposition 1 from the model. This result is supported by evidence from our OLS specification that controls for numerous firm and economic-wide variables, our FE specification that controls for time-invariant unobserved firm-level characteristics, and our PSM specification, which conditions on import

\[25\] As a robustness check, we also considered a version of the specification in (16) that included a continuous measure of imports instead of the importing indicator variable, where the imports are defined at the firm level as the total value of imports. Results from this specification were qualitatively similar to those reported in Table 2.
propensity according to observed firm characteristics. Consistent with Proposition 2, we also find no robust evidence that direct importing retail firms adjust their sales-cost ratios, relative to other firms, in response to exchange rate movements. This result is supported by evidence from our OLS, FE, and PSM specifications. Together, these two results support the central point of our analysis, which is that the import channel is crucial for the transmission of exchange rate movements to retail firm sales and prices (see equations (9) and (12)). Finally, we also find evidence that firms in close proximity to the Canada-U.S. border experience losses in sales, relative to firms further away from the border, due to exchange rate appreciations. This result is supported by evidence from our OLS and FE specifications, although results from the PSM specification are not statistically significant. Our OLS and FE results are consistent with the cross-border shopping mechanism that is built into our model, where exchange rate appreciations lower the cost of cross-border goods, thus attracting domestic consumers to foreign retailers at the expense of domestic retailers (see equation (9)). Given this supporting evidence for the theoretical foundations of the model in section 2, in the next section we turn to quantifying the model-derived exchange rate elasticities of aggregate retail sales and the retail price index.

4 Model-based Analysis

In this section we estimate the exchange rate elasticities of aggregate retail sales and the price index using the model-derived equations (9) and (12) respectively. We begin by discussing the model parameter estimates that are used in estimating both of these elasticity equations.

4.1 Model Parameter Estimates

Our elasticity equations require estimates of the following model parameters: the source country-specific exchange rate elasticity of variable importing trade costs, $\varepsilon_{E}^{Tn}$; the exchange rate elasticity of the cost of cross-border shopping, $\varepsilon_{E}^{TB}$; the import share, $P_nQ_n/PQ$, for each country $n$, and the CES elasticity of substitution, $\sigma$. Below we estimate each of these model parameters using a combination and firm-level and product-level data. We also require an estimate of the ratio of cross-border shopping expenditures relative to Canadian retail expenditures, $P_BQ_B/PQ$. As discussed below, for this ratio we make use of estimates from previous research. Throughout our model-based empirical analysis we
consider three import source countries/regions: the U.S., China, and the rest of the world (ROW).

4.1.1 Exchange Rate Elasticity of Import Trade Costs ($\varepsilon_{\tau E}^{n}$)

We use the theoretical model to derive two estimating equations that are used to identify the source country-specific exchange rate elasticity of import trade costs, $\varepsilon_{\tau E}^{n}$. In both cases we follow a similar approach in deriving an estimating equation from the model that depends on variable trade costs, $\tau_{n}$, and then we substitute the following reduced-equation for variable trade costs into the estimating equation:

$$\ln(\tau_{n,t}) = \alpha_0 + \alpha_1 \ln(E_{USD/CAD,t}) + \alpha_2 t$$  \hspace{1cm} (17)

where we have added a time subscript to $\tau_{n}$ to reflect the time variation in import trade costs; the variable $t$ is a time trend variable; and $E_{USD/CAD,t}$ is the USD-CAD nominal exchange rate.\textsuperscript{26} The coefficient $\alpha_1 = \varepsilon_{\tau E}^{n}$ is the country-specific exchange rate elasticity of variable import costs, which is a key parameter needed for our model-based empirical analysis. As noted below, our estimation framework involves running country-specific regressions, and therefore any time-invariant country-specific factors affecting trade costs (e.g. distance) are absorbed in the coefficient $\alpha_0$.

The dependent variable in our first estimating equation is the logarithm of country-specific firm-level purchases (i.e. imports) divided by firm-level domestic purchases.\textsuperscript{27} The Melitz (2003) structure of our model implies that this ratio is equal to $1 - \sigma$ multiplied by logarithm of country-specific variable imports costs, $\tau_{n}$. Substituting in equation (17) for this term yields our first estimating equation:

$$\ln \left( \frac{\text{purchases}_{i,n,t}}{\text{purchases}_{i,0,t}} \right) = (1 - \sigma)\alpha_0 + (1 - \sigma)\alpha_1 \ln(E_{USD/CAD,t}) + (1 - \sigma)\alpha_2 t + u_{i,n,t}$$  \hspace{1cm} (18)

where $\text{purchases}_{i,n,t}$ is the value of retail firm $i$’s imports from country $n$, and $\text{purchases}_{i,0,t}$ is the value

\textsuperscript{26}We use the USD-CAD nominal exchange rate rather than other bilateral exchange rates or the nominal effective exchange rate for Canada to accord with the dominance of USD invoicing in Canadian imports. Our data does not include information on currency of invoice, but Devereux et al. (2017) report that roughly 92% of Canadian imported goods (in value terms) were invoiced in USD during the period 2002-2008, which overlaps with our period of study. This suggests that, for nearly all importing firms in Canada, changes in the USD-CAD nominal exchange rate are more relevant than changes in other bilateral Canadian exchange rates.

\textsuperscript{27}In our model-based analysis we use purchases rather than cogs as our measure for the intermediate input variable. Recall from section 3 that cogs is defined: $\text{cogs}_{i,n,t} = \text{purchases}_{i,n,t} - \Delta \text{inventories}_{i,n,t}$. In theory cogs is a more accurate measure as it accounts for inventories, but unfortunately we do not observe country-specific changes in inventories. However, we note that at the firm-level the total change in inventories is typically very small relative to purchases. Theoretically, we do not make a distinction between purchases and cogs.
of the retailer’s domestic purchases. We approximate domestic purchases by subtracting the value of the firm’s total imports (from all countries) from its total purchases of goods for resale. For each importing source country, equation (18) is estimated by panel fixed effects regression.\textsuperscript{28} In our regressions we include NAICS 4-digit industry dummies and cluster our standard errors at the firm-level. Given an estimate of $\sigma$, we can calculate our key parameter of interest $\alpha_1 = \varepsilon^{\tau_n} E$ from the regression coefficient on the exchange rate variable $\ln(E_{USD/CAD,t})$. As discussed in section 4.1.4, we use an estimate of $\sigma = 4.02$ in our model-based analysis.

The dependent variable for our second estimating equation is the logarithm of retailer $i$’s imports from country $n$, $\ln(purchases_{i,n,t})$, which from our model implies the following estimating equation:

$$\ln(purchases_{i,n,t}) = \ln((\sigma - 1)f) + (1 - \sigma)\ln(\tau_{n,t}) + (1 - \sigma)\ln(\varphi_{0,t}) + \sigma\ln(\varphi_{i,t})$$ (19)

where we have added a time subscript to the operating cut-off, $\varphi_{0,t}$, and a time and firm subscript to the firm’s productivity parameter, $\varphi_{i,t}$, to reflect the inter-temporal and cross-sectional variation in these parameters. These parameters did not appear in equation (18) because they are in both the numerator and denominator of the import-domestic purchases ratio. Relative to the first estimating equation, the presence of cut-off and firm-specific productivity parameter make identification more challenging. However, an advantage of the second estimating equation is that it is directly comparable to the approach we will use to estimate the exchange rate elasticity of the cost of cross-border shopping, $\varepsilon^{\tau_B E}$. Using a similar methodology to estimate $\varepsilon^{\tau_n E}$ and $\varepsilon^{\tau_B E}$ is important, since the exchange rate elasticities of aggregate retail sales and prices depend critically on the relative magnitudes of these parameters.

We control for the firm-specific productivity parameter in equation (19) estimating a panel fixed effects regression. To control for time variation in the operating cut-off, we make use of the free-entry condition: $\tilde{\pi}_t = f_e (1 - G(\varphi_{0,t}))^{-1}$. Assuming that the distribution function $G$ is invertible, we rearrange this condition to express the logarithm of the operating cut-off as a non-linear function of average retail profits $\tilde{\pi}_t$ and the fixed cost of entry, $f_e$. We approximate this non-linear function using a fourth order polynomial in average profits, which we denote $h(\tilde{\pi}_t)$.\textsuperscript{29} As in our first estimating equation, we

\textsuperscript{28}We note that according to our theory, the OLS estimator is unbiased, since the firm-level heterogeneity parameter, $\varphi$, cancels in the import-domestic cost ratio in equation (18). However, we estimate the fixed effects specification to control for other time-invariant dimensions of heterogeneity.

\textsuperscript{29}We calculate average profits by subtracting retailers mean annual rent and leasing expenses (our measure of fixed costs)
substitute equation (17) into equation (19), which allows us to re-write our second estimating equation as follows:

\[
\ln(purchases_{i,n,t}) = \zeta_0 + (1 - \sigma)\alpha_1 \ln(E_{USD/CAD,t}) + (1 - \sigma)\alpha_2 t + h(\tilde{\pi}_t) + u_{i,n,t} \tag{20}
\]

The right-hand side of our second estimating equation is the same as (18), expect for the inclusion of the quadratic profit function and the redefined constant term, \( \zeta_0 = \ln((\sigma - 1)f) + (1 - \sigma)\alpha_0 \). As in the first estimating equation, we include NAICS 4-digit industry dummies and cluster our standard errors at the firm-level. For each importing country, equation (20) is estimated by panel fixed effects regression. For the profit and import cost variables, we convert from nominal to real profits using the expenditure-based consumer price index (CPI) for Canada. The key parameter of interest is again \( \alpha_1 = \varepsilon_{E,n}^T \), which is calculated post-estimation from the coefficient on the exchange rate variable \( \ln(E_{USD/CAD,t}) \), and using our estimate of \( \sigma = 4.02 \).

The results from estimating regression equations (18) and (20) are reported in Table 3 columns 1–3 and 4–6 respectively. For equation (20), our preferred specification, the estimates of the coefficient on nominal exchange rate, \( \ln(E_{USD/CAD,t}) \), are positive and statistically significant at the 5% level across all three source countries. This is consistent with the logic that a CAD appreciation lowers the cost of imported goods (priced in USD) relative to goods that are sourced domestically (priced in CAD), which leads to a rise in the import share. For both specifications, our estimate of this coefficient is largest for imports from China, slightly lower for imports from the US, and lower still for imports from ROW.

To derive values for \( \varepsilon_{E,n}^T \), we simply divide our estimated coefficients on the nominal exchange rate by \( 1 - \sigma \) as reflected in equations (18) and (20). Using the value of \( \sigma = 4.02 \), our country-specific exchange rate elasticities of import costs (in absolute value) are \( |\varepsilon_{E,n}^{US}| = 0.238 \), \( |\varepsilon_{E,n}^{China}| = 0.323 \), and \( |\varepsilon_{E,n}^{ROW}| = 0.201 \). The relatively large elasticity estimate for China, combined with the rapid growth in Chinese imports during our study period, implies that there were considerable cost savings to retailers that imported from China. This, according to our model, will contribute to deflationary pressure and Canadian retail sales growth in response to an appreciation of the CAD.

We also estimated p-values for the null hypothesis that these exchange rate coefficient estimates are from mean variable profits. As defined by the model, mean variable profits are expressed as mean sales divided by the elasticity of substitution, \( \sigma \).

Standard errors are clustered at the firm level. *** p<0.01, ** p<0.05, * p<0.1. The estimates of |ε_E|^n are calculated using the coefficient on the exchange rate variable, (1−σ)ε_E^0, and our estimate of σ=4.02 from Table 5.
equal across all three source countries, which we reported in the row below the R-squared values in table 3. The p-values are high enough that we fail to reject the null hypothesis at any conventional level of statistical significance. Nevertheless the economic significance of the differences in the estimates is large, as the trade cost elasticity estimate for China is more than one and a half times larger than for ROW. We therefore use the source-country specific elasticities in columns 4–6 as our benchmark estimates in our model-based analysis.

4.1.2 Exchange Rate Elasticity of Cross-border Shopping Costs ($\varepsilon_{EB}^T$)

Our approach to estimating the exchange rate elasticity of cross-border shopping, $\varepsilon_{EB}^T$, closely follows the methodology used in (20) to estimate $\varepsilon_{En}^T$. From equation (4), the logarithm of cross-border expenditures can be written as:

$$
\ln(P_{B,t}Q_{B,t}) = \ln(\sigma f \rho^{1-\sigma}) + (1 - \sigma)\ln(\tau_{B,t}) + (1 - \sigma)\ln(\phi_{0,t})
$$

(21)

As in (20), we control for the operating cutoff using a fourth order polynomial in average profits, defined $h(\tilde{\pi}_t)$.\(^{30}\) For cross-border trade costs, $\tau_{B}$, we again make use of the reduced form specification given by equation (17). We therefore re-write our cross-border shopping estimating equation (21) as follows:

$$
\ln(P_{B,t}Q_{B,t}) = \ln(\sigma f \rho^{1-\sigma}) + (1 - \sigma)\alpha_0 + (1 - \sigma)\alpha_1\ln(E_{USD/CAD,t}) + (1 - \sigma)\alpha_2 t + h(\tilde{\pi}_t) + u_t
$$

(22)

where $P_{B,t}Q_{B,t}$ is quarterly Canadian aggregate expenditures on cross-border shopping.\(^{31}\) We report estimation results for specifications with and without the quadratic profit function, and in some specifica-

---

\(^{30}\)As equation (21) is estimated using quarterly data, we require quarterly data on average profits. Following the specification of equation (20), we calculate average profits by subtracting retailers mean rent and leasing expenses from mean variable profits. We do not observe quarterly data on rent and leasing expenses so we calculate this variable by dividing annual mean rent and leasing expenses by four. As in the specification of equation (21), mean variable profits are defined as mean quarterly sales divided by the elasticity of substitution, $\sigma$. We calculate average quarterly Canadian retail sales using Statistics Canada table 080-0020 (seasonally adjusted aggregate retail sales from the Monthly Retail Trade Survey, which excludes the sales of non-store retailers), and Statistics Canada table 527-0013 (quarterly estimates for the number of Canadian firms for the retail sector).

\(^{31}\)These data are sourced from Statistics Canada table 387-005. This table reports seasonally adjusted quarterly data from Canada’s international travel account for the period from 1986 (quarter 1) to 2012 (quarter 2), including figures for total spending abroad by Canadians. Total spending abroad includes purchases of both goods and services. Some of these expenses are incurred during trips that unrelated to cross-border shopping, and hence these figures provide an overestimate of cross-border shopping expenses. However, this series provides the closest coverage to our period of interest (2000-2012) among the available resources that provide approximate measures of Canadian cross-border shopping expenses.
tions we also include a post-9/11 dummy variable (beginning in quarter 4 of 2001). For the cross-border expenditure and import cost variables, we convert from nominal to real profits using the annual average of monthly aggregate consumer price index (CPI) for Canada reported by Statistics Canada. We estimate equation (22) by OLS using heteroskedastic-robust standard errors.

The results from estimating equation (22) are reported in Table 4. Across all columns, the estimate of the coefficient on nominal exchange rate, \( \ln\left(E_{USD/CAD,t}\right) \), is positive and statistically significant at the 5% level. This is consistent with our prior that a CAD appreciation lowers the cost of cross-border shopping to the US relative to goods that are sold in Canada, which encourages cross-border shopping expenditures. Columns 3 and 4 correspond to estimates from (22), which assumes a quadratic profit function. Results from our preferred specification, which assumes a quadratic profit function and controls for the drop in cross-border shopping after 9/11, are reported in column 4.

Robust standard errors are in parentheses. *** \( p<0.01 \), ** \( p<0.05 \), * \( p<0.1 \). The estimates of \( |\epsilon_{E}^\tau B| \) are calculated using the coefficient on the exchange rate variable, \((1-\sigma)\epsilon_{E}^n\), and our estimate of \( \sigma=4.02 \) from Table 5.

To derive a value for \( \epsilon_{E}^\tau B \), we divide our estimated coefficient on the nominal exchange rate by \((1-\sigma)\) as reflected in equation (22), using a value of \( \sigma = 4.02 \). The exchange rate elasticity of cross-border shopping costs is \( |\epsilon_{E}^\tau B| = 0.0801 \). Note that the magnitude of this estimate is considerably smaller than our estimates of the import trade cost elasticities, \( |\epsilon_{E}^\tau US| = 0.238 \), \( |\epsilon_{E}^\tau China| = 0.323 \), and \( |\epsilon_{E}^\tau ROW| = 0.201 \). This suggests that variable import costs are more responsive than the cost of cross-
border shopping to changes in the exchange rate.\textsuperscript{32}

### 4.1.3 Import Share ($P_n Q_n / PQ$)

For our model-based analysis we require estimates of the share of source-country specific imports in total retail purchases. We use two different approaches to calculating the country-specific import shares. For our first method, we calculate the country-specific import shares in total consumer good purchases from the input-output (IO) tables made publicly available by Statistics Canada.\textsuperscript{33} Columns 1–3 in table 5 report the share of retail imports from the US, China, and the rest of the world, respectively, as calculated from the Statistics Canada IO tables.

Our second approach to calculating the import shares makes use of the firm-level data from Statistics Canada’s IR. Relative to the first approach, our IR-based measures have the advantage of using direct evidence on the value of firm-level imports. However, as we discuss in greater detail below, a disadvantage of the IR-based measures is that the resulting import shares are very likely biased downwards. Columns 4–6 in table 5 report IR-based measures of the share of retail imports from the US, China, and the rest of the world, respectively. We note that the numerator in columns 4–6 is the sum of both direct and indirect imports from each respective country. Direct imports is the aggregate value of imports by the retail sector (NAICS 44-45) based on the Import Register (IR).\textsuperscript{34} We calculate country-specific indirect imports as follows: \(\text{Indirect Imports}_{n,t} = \text{Value Imports}_{W,n,t} \times \theta_{W,R,t} \times \mu_{W,t}\), where \(\text{Value Imports}_{W,n,t}\) is the aggregate value of wholesale sector (NAICS 41) imports from country \(n\) in year \(t\); \(\theta_{W,R,t}\) is the fraction of aggregate wholesale sector total operating revenue that is sold to the retail sector in year \(t\); and \(\mu_{W,t}\) is the wholesaler

\textsuperscript{32}We also considered several alternative specifications that are not reported in Table 4. As an alternative to the nominal exchange rate, we considered the Canadian-Dollar Effective Exchange Rate Index constructed by the Bank of Canada. This yields similar results as those yielded with the nominal exchange rate. As additional regressors, we considered an interaction term between the nominal exchange rate and the 9/11 indicator variable, and a “great trade collapse” indicator variable that equals 1 from the fourth quarter of 2008 to the fourth quarter of 2009 (inclusive), and zero in all other quarters. Both of these variables yielded insignificant coefficients, and their inclusion had little effect on the estimate of the coefficient on nominal exchange rate, \(\ln(E_{USD/CAD,t})\).

\textsuperscript{33}In section 3 of the online appendix, we provide a detailed description of the method we use to estimate the import shares reported in columns 1–3. These estimates cover a broad range of core consumer goods, including final motor vehicles, gasoline, consumer food products, clothing, household goods, and personal care goods.

\textsuperscript{34}We calculate direct imports for the retail sector and wholesale sector using micro data from Statistics Canada’s Import Register. For the years 2010 forward, aggregate product-level import data are also available in the Statistics Canada table 228-0101. Our aggregates differ slightly from those reported Table 228-0101 due to recent updates in Statistics Canada’s definition of enterprises and their NAICS industry.
mark-up in year $t$, calculated as the total operating revenue relative to the total costs of goods sold in the sector using data from Statistics Canada tables 081-0014 and 081-0017. 45 The denominator in columns 4–6 is the aggregate value of retail sector purchases of goods for resale, calculated from Statistics Canada tables 080-0011, 080-0012, 080-0023, 080-0030, and 080-0028.

Columns 1–3 provide country-specific measures of the import share calculated from Statistics Canada input-output (IO) tables 36-10-0403-01, 36-10-0424-01, 36-10-0418-01 and 36-10-0417-01, and UN Comtrade data. Columns 4–6 provide country-specific measures of the import share of purchases in the Canadian retail sector calculated from the Statistics Canada’s Import Register (IR). The numerator in columns 4–6 is the sum of direct and indirect imports from each respective country. Direct imports is the aggregate value of imports by the retail sector (NAICS 44-45). Indirect imports are defined: Indirect Imports$_t = ValueImports_{W,t} \times \theta_{WR,t} \times \mu_{W,t}$, where ValueImports$_{W,t}$ is the aggregate value of wholesale sector (NAICS 41); $\theta_{WR,t}$ is the fraction of aggregate wholesale sector total operating revenue that is sold to the retail sector in each year as estimated from the micro data in the Annual Wholesale Trade Survey; and $\mu_{W,t}$ is the wholesaler markup, calculated as the total operating revenue relative to the total costs of goods sold in the sector using data from Statistics Canada tables 081-0014 and 081-0017. The denominator in columns 4–6 is the aggregate value of retail sector purchases of goods for resale, calculated from Statistics Canada tables 080-0011, 080-0012, 080-0023, 080-0030, and 080-0028. Column (7) is our benchmark measure of the CES mark-up, $\mu$, defined as the ratio of aggregate retail sales relative to the costs of goods sold (COGS), and calculated from Statistics Canada tables 080-0011, 080-0012, 080-0023, 080-0030, and 080-0028. Column (8) is the value of the elasticity of substitution $\sigma$, that is implied by the value of the mark-up, $\mu = \sigma/(\sigma - 1)$.

Taking the sum across columns 1–3, our IO-based measure of the overall import share in total retail purchases rose over our period of study from 0.4664 in 2002 to 0.5091 in 2012. The import growth

---

45 There are two assumptions that are implicit in our indirect import calculation. First, by multiplying the value of imports by $\theta_{WR,t}$, we assume that the fraction of wholesalers country $n$ imports sold to the retail sector is equal to fraction of revenue that wholesalers obtain from the retail sector. Second, we assume that wholesalers charge a constant mark-up on the imported goods from each country that is equal to their aggregate mark-up of total operating revenue relative to their cost of goods sold. We acknowledge that these assumptions are unlikely to hold in reality, however we view our approach as the best approximation of retail indirect imports given the data that is available for our analysis.
during this period was largely driven by the Chinese imports, which accounted for 7.5% of total imports in 2002 and 15.3% in 2012. In contrast, imports from the US and ROW accounted for 55.4% and 37.2% respectively in 2002, and fell to 48.4% and 36.4% respectively by 2012.

Although the IO and IR-based import shares have similar dynamics, the level IO-based measures are much larger. Summing across source countries and averaging over the period 2002–2012, the average total import share based on the IO tables is 0.48, which is nearly 2.5 times the same average for the IR. The IR import shares are likely biased downwards for a number of reasons. While we account for indirect imports through the wholesale sector, there are other sectors that act as intermediaries for final goods that are sold by retailers. Importantly, motor vehicles and parts dealers accounted for 26% of the total cost of goods sold in the retail sector in 2012, and imports account for a large fraction of sales in this industry. However, auto manufacturers are largely responsible for finished motor vehicles imports, and our IR measure fails to capture foreign vehicles that are imported via the manufacturing sector. At the same time, there are likely also inaccuracies in our IO-based measures of the import shares. For example, the IO measures identify retail goods based on an input-output commodity classification (IOCC). Any such distinction is imperfect, recognizing that many products might be used as both for consumption and as intermediate or capital goods, depending on the purchaser. However, unlike the IR-based measure, there are no clear reasons why the inaccuracies of the IO-based approach should result in a downward or upward bias in our import share measures. For this reason use the IO-based measures of the import shares in our benchmark specification when estimating the aggregate retail sales and price index elasticity equations. However we also present these elasticity estimates using the IR-based measures, and discuss the sensitivity of our results to this alternative specification.

---

36 Sourced from Statistics Canada table 0800030.
37 According to Statistics Canada data, the total value of Canadian imports of motor vehicles and parts was roughly $63 billion in 2012, and about $36 billion of these imports were finished passenger cars, light-trucks and SUVs. Meanwhile, total imports by firms classified in the “Transportation Equipment Manufacturing” industry were roughly $71 billion in 2012, which is close to the $63 figure for total motor vehicles and parts imports. If we assume that these firms are not importing finished vehicles, then roughly 60% of their imports must be in inputs that are not classified as motor vehicle parts, which is unlikely. More likely is that these firms are importing a significant share of Canada’s total finished vehicles imports, and that finished vehicles and vehicle parts make up the preponderance of total “Transportation Equipment Manufacturing” industry imports.
38 For example, one of the commodity groups that we include in our set of retail goods is “Mayonnaise, salad dressing & mustard”. These products are sold as retail goods to consumers, but are also surely sold to restaurants and food producers as inputs into production.
4.1.4 Elasticity of Substitution ($\sigma$)

We cannot identify the elasticity of substitution, $\sigma$, without imposing parametric assumptions on the ex-ante productivity distribution, $G(\varphi)$. To obtain a benchmark value of $\sigma$ for our analysis, we assume that all firms are homogenous in productivity and normalize aggregate productivity to one. In this case the CES mark-up, $\mu$, is equal to the aggregate sales-cost ratio, $\mu = \sigma/(\sigma - 1) = PQ/COGS$. Using this formula, we estimate a value of $\mu$ in column (6) of table 5 using Statistics Canada data, while column (7) shows the corresponding implied value of $\sigma$.\textsuperscript{39} We are reassured that $\sigma$ is very stable over our observation period, and by the fact that its average value, $\sigma = 4.02$, is very close to 4, which is the value used in Melitz and Redding (2013) and several other papers in the empirical trade literature.

It is worth noting that our results are not particularly sensitive to the value of $\sigma$ that is used in estimating our model-derived aggregate exchange rate elasticity equations. In fact, our estimate of the exchange rate elasticity of aggregate retail sales, equation (9), is unaffected by the value of $\sigma$ that is used.\textsuperscript{40} Furthermore, in estimating the exchange rate elasticity of retail prices, equation (10), the parameter $\sigma$ affects the magnitude but not the sign of our estimate.\textsuperscript{41} In this respect, our qualitative results on the effect of exchange rate variation on aggregate retail sales and prices are very robust to alternative specifications of the parameter $\sigma$.

4.1.5 Cross-border Shopping Share of Canadian Retail Expenditures ($P_BQ_B/PQ$)

We rely on existing literature for our estimate of the ratio of cross-border shopping expenditures relative to Canadian retail expenditures, $P_BQ_B/PQ$. Corbi (2014) estimates this ratio using data from Statistics Canada’s Canadian System of Macroeconomic Accounts (CSMA) for the period 2006-2012. Included in Corbi’s estimate of cross-border shopping expenditures is the outlays that Canadian households make on goods that are purchased in the United States and then brought back to Canada, goods that are delivered to Canada by post and courier, and motor vehicle imports purchased directly by consumers. These figures are derived for the CSMA from several different sources.\textsuperscript{42}

\textsuperscript{39}Our estimates in columns (6) and (7) use Statistics Canada tables 080-0011, 080-0012, 080-0023, 080-0030, and 080-0028.

\textsuperscript{40}This is because elasticity equation (9) only requires an estimate of $(\sigma - 1)\varepsilon^1_E$ and $(\sigma - 1)\varepsilon^B_E$, which are regression coefficients on the exchange rate variable that are estimated in sections 4.1.1 and 4.1.2 respectively.

\textsuperscript{41}Although $\sigma$ does not appear directly in equation (10), we need an estimate of this parameter to obtain estimates of $\varepsilon^1_E$ and $\varepsilon^B_E$ from the regression results in sections 4.1.1 and 4.1.2 respectively.

\textsuperscript{42}These sources include: the International Travel Survey (ITS) collects reported spending from respondent Canadian residents on overnight and same-day trips to the U.S.; customs data, combined with Canada post data, permit calculation of
Corbi (2014) provides a range of estimates for the total value of cross-border shopping expenditures based on different assumptions regarding expenses incurred during trips to the U.S. that are not brought back into Canada (e.g. meals abroad, accommodation, etc.). The estimates are based on both annual and quarterly seasonally-adjusted series. For the purposes of our analysis, we use the values from the “high spending” scenario in Corbi (2014), since this is the scenario that is most closely related to how we model cross-border shopping.\footnote{In particular, we choose the “high spending” scenario because in our model, $\tau_B$ includes all travel costs that are associated with cross-border shopping.}

In Figure 2, we reproduce the ratio of cross-border shopping expenditures relative to Canadian retail expenditures, using the “high spending” scenario from Corbi (2014). From the first quarter of 2006 to the fourth quarter of 2012, the cross-border shopping share fluctuated in the range from 1.6% to 2.4%. This share fluctuates positively with the exchange rate, which is consistent with a negative value for $\varepsilon_{BE}^T$ as estimated in section 4.1.2. As we do not have estimates of cross-border shopping expenditures for the duration of our observation period, we set $P_BQ_B/(PQ)$ at a constant value equal to 1.96%, which is the average value of the “high spending” scenario ratio reported by Corbi (2014) over the period 2006-2012.

### 4.2 Exchange Rate Elasticity of Retail Sales

In this section we present our estimates of the exchange rate elasticity of aggregate retail sales. Our estimates use our model derived elasticity equation and the model parameter estimates from section 4.1. Our elasticity equation, also reported as equation (9) in section 2, is the following:

$$\varepsilon_{PQ}^E = (\sigma - 1) \frac{P_BQ_B}{PQ} \left( \sum_{n=1}^{N} \left( |\varepsilon_{E}^{\tau_n} \frac{P_nQ_n}{PQ} \right) - |\varepsilon_{BE}^T| \right)$$

This equation allows us to distinguish the positive contribution of lower-priced imports, captured by the weighted import trade cost elasticity, $\sum_{n=1}^{N} \left( |\varepsilon_{E}^{\tau_n} \frac{P_nQ_n}{PQ} \right)$, and the negative contribution of lower-priced cross border goods, captured by $|\varepsilon_{BE}^T|$, for aggregate retail sales.

Column 1 of table 6 reports our estimates of the weighted import trade cost elasticity from 2002 to

---

\footnote{In particular, we choose the “high spending” scenario because in our model, $\tau_B$ includes all travel costs that are associated with cross-border shopping.}

---
2012, using the IO-based source country specific import shares, \( P_nQ_n/(PQ) \), as reported in Table 5.\(^{44}\) This weighted elasticity grew by roughly 12\% from 2002 to 2012, and this growth is almost entirely due to change in China’s contribution. China’s contribution to the weighted elasticity grew both because Canadian retail imports from China grew rapidly over this period, and because our estimated the Chinese trade cost elasticity, \( |\varepsilon_E^{\tau_{\text{China}}}| \), is larger than the trade cost elasticity for the U.S. and the ROW.

In column 4 we present our benchmark estimates of the exchange rate elasticity of aggregate sales, \( \varepsilon_E^{PQ} \), which use our IO-based measure of the import shares. The aggregate sales elasticity is positive in all years, as the IO-based weighted import trade cost elasticity is greater than our estimate of the exchange rate elasticity of cross-border shopping, \( \varepsilon_E^{TB} = 0.0801 \). The aggregate sales elasticity increased by 49\% over our sample period, and this growth is again due to the growth of Chinese imports. The magnitude of all of the retail sales elasticities reported in this section are small, with a 10\% increase in the exchange rate resulting 0.0241\% increase in aggregate retail sales in 2012. Mechanically, the small magnitude of our sales elasticity estimates is due to the fact that cross-border shopping accounts for only 2\% of household expenditures. As households already spend 98\% of their budget on domestic retail goods, the added sales from consumers switching away from the cross-border good results in a very small percentage increase in domestic sales.

Column 3 reports the counterfactual elasticity estimates for the years 2002–2012 under the case where retail import shares are set to zero for all source countries, \( P_nQ_n/(PQ) = 0 \) for all \( n \). Under this counterfactual with no importing, the effect of an exchange rate appreciation on sales is negative, as the exchange rate elasticity of aggregate retail sales is -0.0047. Comparing this counterfactual to our benchmark estimates in column 4 shows that the mitigating effects of importing on retail sales more than offset the negative effects cross-border shopping, such that the net effect of an appreciation on retail sales is positive in all years in our observation period.

We next report aggregate sales elasticity estimates using import shares derived from the IR, which are reported in table 5. Since our IR import shares are much smaller than our measures constructed using the IO tables, our measures of the weighted import weighted import trade cost elasticity, \( \sum_{n=1}^{N} (|\varepsilon_E^{\tau_{\text{n}}}|P_nQ_n/(PQ)) \), are also significantly smaller. In fact, in all years from 2002–2012, this weighted elasticity is less than the exchange rate elasticity of cross-border shopping, \( \varepsilon_E^{TB} = 0.0801 \). Hence, our estimates of the ag-

\(^{44}\)All specifications in Table 6 use the following parameter estimates, which are assumed to be constant overtime: \( \sigma = 4.02, P_BQ_B/(PQ) = 0.0196, |\varepsilon_E^{\beta_B}| = 0.0801, |\varepsilon_E^{\tau_{\text{US}}}| = 0.238, |\varepsilon_E^{\tau_{\text{China}}}| = 0.323, \text{ and } |\varepsilon_E^{\text{ROW}}| = 0.201.\)
Table 6: Elasticity of Retail Sales with Respect to the Exchange Rate

| Year | \( \sum_{n=1}^{N} \frac{|\epsilon_{\tau n}|P_nQ_n}{PQ} \) | \( \sum_{n=1}^{N} \frac{|\epsilon_{\tau n}|P_nQ_n}{PQ} \) | No Importing | \( \frac{\epsilon_{\tau n}}{PQ} \) | \( \frac{\epsilon_{\tau n}}{PQ} \) | \( \frac{\epsilon_{\tau n}}{PQ} \) |
|------|---------------------------------|---------------------------------|--------------|----------------|----------------|----------------|
| 2002 | 0.1076                          | 0.0387                          | -0.00473     | 0.00162        | -0.00245        |
| 2003 | 0.1038                          | 0.0328                          | -0.00473     | 0.00140        | -0.00279        |
| 2004 | 0.1048                          | 0.0432                          | -0.00473     | 0.00146        | -0.00218        |
| 2005 | 0.1085                          | 0.0484                          | -0.00473     | 0.00167        | -0.00187        |
| 2006 | 0.1112                          | 0.0521                          | -0.00473     | 0.00184        | -0.00166        |
| 2007 | 0.1139                          | 0.0529                          | -0.00473     | 0.00199        | -0.00161        |
| 2008 | 0.1169                          | 0.0491                          | -0.00473     | 0.00217        | -0.00183        |
| 2009 | 0.1137                          | 0.0486                          | -0.00473     | 0.00198        | -0.00186        |
| 2010 | 0.1174                          | 0.0544                          | -0.00473     | 0.00220        | -0.00152        |
| 2011 | 0.1193                          | 0.0515                          | -0.00473     | 0.00232        | -0.00169        |
| 2012 | 0.1209                          | 0.0478                          | -0.00473     | 0.00241        | -0.00191        |

Column 3 reports the elasticity when imports are set to zero. All specifications use the following parameter estimates, which are assumed constant overtime: \( \sigma = 4.02 \), \( P_nQ_n/(PQ) = 0.0196 \), \( |\epsilon_{\tau B}| = 0.0801 \), \( |\epsilon_{\tau US}| = 0.238 \), \( |\epsilon_{\tau China}| = 0.323 \), and \( |\epsilon_{\tau ROW}| = 0.201 \). Estimates of \( P_nQ_n/(PQ) \) for each respective country in each year are from Table 5.

Aggregate retail sales elasticity using the IR import shares, reported in column 5, are negative for all years. This indicates that, according to the IR-based measures of the import share, the negative impact of cross-border shopping outweighs the mitigating effects of importing, hence appreciations had negative impact on Canadian retail sales throughout the 2002–2012 period.

For the final exercise in this section we calculate the ‘break-even’ import share, Import \( \text{Share}^{*} \), which we defined as the import share at which the exchange rate elasticity of aggregate retail sales is zero. For the purpose of this exercise we consider an aggregate import cost elasticity that is equal to the three country average, \( |\epsilon_{\tau}| = \sum_{n=1}^{N} |\epsilon_{\tau n}|/3 = 0.254 \). The break-even import share is then defined by the equation \( |\epsilon_{\tau}|(Import \text{Share}^{*}) = |\epsilon_{\tau B}| = 0.0801 \). This equation implies that the break-even import share is 0.315. Thus, our conclusions regarding the sign of the effect of an exchange rate appreciation on aggregate retail sales depends on our choice of methodology in calculating import shares. For the IR-based measures, the import share (aggregated across all source countries) is less than the break-even value for all years during the period 2002–2012, which implies that an appreciation has negative effect on sales. Conversely, the IO-based import share is larger than the break-even value for all years during
this period, suggesting that an appreciation increases retail sales.\textsuperscript{45} As we discussed in section 4.1.3, the IR-based measures of the import shares are likely biased downwards, which leads us to favour the IO-based measures as our preferred specification and conclude that appreciations have a positive effect on aggregate retail sales. While the sign of this elasticity depends on our specification, we note that note both the IO and IR-based sales elasticities show the same dynamic upward trend over our sample period, reflecting the of Chinese import growth in increasing the responsiveness of retail sales to exchange rate appreciations.

### 4.3 Exchange Rate Elasticity of the Retail Price Index

In this section we present our estimates of the exchange rate elasticity of the retail price index. Our elasticity equation, also reported in equation (10) in section 2.4, is the following:

\[
\varepsilon_P = -\frac{\bar{P}\bar{Q}}{PQ} \sum_{n=1}^{N} \left( |\varepsilon_{\tau}^{E} P_n Q_n \right) + \frac{P_B Q_B}{PQ} \left|\varepsilon_{\tau}^{B} E \right| 
\]

Intuitively, the weighted import trade cost elasticity, \(\sum_{n=1}^{N} \left( |\varepsilon_{\tau}^{E} P_n Q_n \right)\), has a deflationary effect in response to an appreciation, as cheaper imports lower retail prices. This term is weighted by the term \(\bar{P}\bar{Q}/(PQ)\), which is the ratio of total expenditures (inclusive of retail and cross-border sales) relative retail expenditures. Meanwhile, the exchange rate elasticity of cross-border shopping prices, \(\varepsilon_{\tau}^{B} E\), has an inflationary effect on retail prices, since greater cross-border shopping leads to a decline in the measure of domestic retail firms. This reduction in the measure of domestic retailers raises the retail price index as a result of the love-of-variety property of CES demand. However, this inflationary effect is very small, as the cross-border elasticity is weighted by the ratio of cross-border shopping expenditures relative to Canadian retail expenditures, \(P_B Q_B/(PQ)\). Using Corbi’s (2014) estimate of \(P_B Q_B/(PQ) = 0.0196\) and our estimate of \(\varepsilon_{\tau}^{B} E = 0.0801\), the inflationary effect of an exchange rate appreciation on retail prices is 0.00157. We show below that this effect is dominated by the deflationary effects from the reduction in import costs in every year from 2002–2012.

Table 7 presents our estimates of the exchange rate elasticity of the retail price index, \(\varepsilon_P\), using the parameter estimates from section 4.1.\textsuperscript{46} We calculate the retail price elasticity using the IO-based

\textsuperscript{45}The IR and IO import shares are calculated by summing across columns 1–3 and 4–6 respectively in table 5.

\textsuperscript{46}The ratio \(PQ/(PQ)\) is calculated using our estimate of \(P_B Q_B/(PQ) = 0.0196\) from the Corbi (2014), \(PQ/(PQ) = \)}
measure of the import share in column 1, and the IR-based measure in column 2.

The following parameter estimates are used in calculating the elasticities, which are assumed constant overtime: $\sigma = 4.02$, $P_BQ_B/(PQ) = 0.0196$, $|\varepsilon^B_E| = 0.0801$, $|\varepsilon^{US\,E}_E| = 0.238$, $|\varepsilon^{China\,E}_E| = 0.323$, and $|\varepsilon^{ROW\,E}_E| = 0.201$. Estimates of $P_nQ_n/(PQ)$ for each respective country in each year are from Table 5.

Based on the column 1 estimates using the IO data, the elasticity of the aggregate retail price index with respect the exchange rate has a mean value of -0.1132 over the period 2002–2012. This elasticity increases over our period of study by 13%, which mostly reflects growth in Canadian retail imports from China during this period. In column 2 we use the IR import shares, which results in a much smaller mean retail price index elasticity of -0.0466 over the 2002–2012 period. The fact that the price elasticity using the IO data is nearly 2.5 times larger than the IR-based elasticity reflects the fact that the import share estimates are much larger using the IO data. Although the levels differ, in both specifications the price elasticities rise considerably over the observation period.

Overall, results from Table 7 indicate that exchange rate appreciations contributed significantly to deflation in Canada’s retail price index over the 2002–2012 period.

4.4 Discussion

Our results in sections 4.2 and 4.3 provide evidence that the import cost channel was an important contributor to the exchange rate elasticities of aggregate retail sales and the retail price index for Canada

$(1 + P_BQ_B/(PQ)) = 1.0196$. 

37

For aggregate retail sales, we find that exchange rate appreciations had a small positive effect that grew throughout this period. If the import cost channel were shut down, our results suggest that retail sales would have declined in response to appreciations in the Canadian dollar. For the retail price index, we find that exchange rate appreciations had a significant deflationary impact on retail prices throughout the period.

Between 2002 and 2012, the Canadian exchange rate experienced an appreciation in value of roughly 57%. According to our benchmark model using the IO-based import shares, this appreciation led to a 0.1% increase in aggregate Canadian retail sales, and 6.5% reduction in the retail price index.47

These results revise several narratives that come out of the existing literature for Canada. Numerous existing studies have found that exchange rate appreciations have a negative impact on Canadian retail sales, and cite the role of cross border shopping in generating this result.48 Importantly, these findings mostly rely on data from the 1990s or earlier, which is an era when retail imports were less important for Canada. Our findings suggest that Canada experienced sizable growth in retail imports throughout 2002–2012, mostly originating from China. This growth put upward pressure on the exchange rate elasticity of Canadian retail sales, contributing significantly to our finding that exchange rate appreciations had a positive effect on aggregate retail sales over this period.49

Regarding the degree of exchange rate pass-through to consumer prices, our estimates fall in a similar range as those that come out of the existing literature.50 Meanwhile, several existing studies have found that this elasticity declined over time for industrialized countries, and for Canada in particular, based on evidence up to the late 1990s.51 Our analysis updates this narrative, as our benchmark results show that

47These figures are calculated by taking the average over the 2002–2012 period of the benchmark elasticity estimates reported in tables 6 (column 4) and 7 (column 1), and multiplying by 57%, which represents the percentage change in the Canada-U.S. nominal exchange rate between 2002 and 2012, based on annual estimates derived from Bank of Canada data.

48See, for example, Baggs et al. (2016).

49As discussed in section 4.2, our findings indicate that the exchange rate elasticity of retail sales would have been negative throughout 2002–2012 if the import channel were shut down. In periods prior to the 2000s, and especially prior to the 1990s, Canadian retail imports might well have been below the threshold where this elasticity turns positive, and hence the aggregate impact of exchange rate appreciations on Canadian retail sales would have been negative.

50For example, Goldberg and Campa (2010) provide estimates for the exchange rate elasticity of the CPI across a set of 21 industrialized countries, and report an average of -0.15. For Canada, Savoie-Chabot and Khan (2015) estimate the long-run elasticity of the Canadian CPI with respect to the nominal Canada-U.S. exchange rate to be roughly -0.06 using quarterly data for the period 1995 to 2013. In a somewhat older study, Bailliu and Bouakez (2004) note that “It has been traditionally estimated that about 20 per cent of a persistent change of in the Canadian dollar is reflected in the core CPI” (pg. 23).

51For evidence related to industrialized countries, see Bailliu and Bouakez (2004) and Goldberg and Campa (2010). For evidence related to Canada, see Bouakez and Rebei (2008).
throughout the 2002–2012 period, this elasticity rose by 13% for Canada, due to the rising importance of consumer goods imports from China.

5 Conclusion

This paper studies the impact of exchange rate movements on retail sector sales and prices in a small open economy. We develop a model that includes retail firm heterogeneity in productivity, importing, and cross-border shopping among consumers. We use the model to derive expressions for the exchange rate elasticities of aggregate retail sales and the retail price index. The sign of the both elasticities is ambiguous, indicating that exchange rate appreciations could have a positive or negative impact on aggregate retail sales and the retail price index, depending on several model parameters.

We then examine firm-level empirical evidence on the impact of exchange rate movements on the sales and sales-cost ratios of Canadian retailers over the 2002–2012 period. Our findings suggest that retail firms that import directly experience higher sales, relative to other firms, due to exchange rate appreciations. We find no evidence that direct importing retail firms adjust their sales-cost ratios relative to other firms in response to exchange rate movements, which suggests that importers fully pass-through the lower cost of imported goods to retail prices. We also find that firms that are close to the Canada-U.S. border, and hence more exposed to pressures from cross-border shopping, experience losses in sales relative to the typical Canadian firm, due to exchange rate appreciations. This evidence is altogether consistent with the mechanisms from the model.

Finally, we quantify the effect of exchange rate appreciations on Canadian aggregate retail sales and the retail price index, using model parameter estimates from Canadian micro data and other sources. Our benchmark results indicate that the negative impact of increased cross-border shopping is more than offset by the positive impact of lower-cost imports for the retail sector, hence the aggregate impact of exchange rate appreciations on retail sales is positive. Meanwhile, we find that appreciations had a deflationary effect on retail prices. From 2002–2012, the Canadian exchange rate appreciated by 57%, which according to our model, led to a 6.5% reduction in the retail price index.

In the context of the literature, our results are largely in line with findings of several other papers. Several studies have found that, while exchange rate pass-through among wholesalers and manufacturers
may be incomplete, pass-through at the retailer level is high.\textsuperscript{52} Our findings corroborate these results, and furthermore bring emphasis to the potential role for direct importing by retail firms in bypassing other firms and, in turn, enhancing exchange rate pass-through. Meanwhile, several studies have found that exchange rate appreciations had a negative impact on Canadian retail sales, and that exchange rate pass-through to retail prices has fallen over time in Canada, based on evidence from before the 2000s (Baggs et al. (2016), Bouakez and Rebei (2008)). Our findings from throughout the 2002–2012 period indicate that, supported by the strength of the Canadian dollar and declining costs of imports from China, the share of imports in Canadian retail goods was both large and increasing over time. This led to a positive impact of exchange rate appreciations on Canadian retail sales, and growth in the degree of exchange rate pass-through to Canadian retail prices over this period.

6 Model Appendix

6.1 Solving the Model

In this section we solve for the remaining variables that determine the equilibrium of the model. In particular, we derive analytical expressions for the equilibrium mass of varieties and aggregate price index.
The mass of varieties is defined \( \bar{M} = M_0 + \sum_{n=1}^{N} (M_n^w + M_n) \), where \( M_0 \) is the mass of domestic varieties; \( M_n^w \) is the mass of retailers indirectly importing from country \( n \); and \( M_n \) is the mass of retailers directly importing from country \( n \). Following Melitz (2003), we define the weighted average productivity, \( \bar{\varphi} \), as follows:

\[
\bar{\varphi} = \left\{ \frac{1}{M} \left[ M_0 \bar{\varphi}(\varphi_0)^{\sigma-1} + \sum_{n=1}^{N} \left( (M_n^w + M_n) \tau_n^{1-\sigma} \bar{\varphi}(\varphi_n)^{\sigma-1} + M_n \left( \tau_n^{1-\sigma} - \tau_n^{1-\sigma} \right) \bar{\varphi}(\varphi_n)^{\sigma-1} \right) \right] \right\}^{\frac{1}{\sigma-1}}
\]

(24)

Using these definitions of \( \bar{M} \) and \( \bar{\varphi} \), we derive an equation for aggregate retail sales as follows:\(^{53}\)

\[
PQ = \int_{\varphi_0}^{\varphi} \left( \frac{\varphi}{\bar{\varphi}} \right)^{\sigma-1} \frac{g(\varphi)}{1 - G(\varphi_0)} M_0 \partial \varphi + \sum_{n=1}^{N} \left( \int_{\varphi_n^{w}}^{\varphi_n} \left( \frac{\varphi}{\varphi_0} \right)^{\sigma-1} \tau_n^{1-\sigma} \frac{g(\varphi)}{1 - G(\varphi_0)} M_0 \partial \varphi \right)
\]

\[
= \bar{M} \left( \bar{\varphi}/\varphi_0 \right)^{\sigma-1} \sigma f
\]

(25)

Next we derive households’ aggregate expenditures on retail goods as a function of \( \bar{\varphi}, \bar{M}, \) and the aggregate price index, \( \bar{P} \). Note that the aggregate price index, \( \bar{P} \), is distinct from the retail price index, \( P \), since the aggregate index incorporates retail prices and the price of the cross-border good.\(^{54}\) We derive an expression for aggregate expenditures on retail goods as follows:\(^{55}\)

\[
PQ = \int_{\varphi_0}^{\varphi} p_0(\varphi, 0)^{1-\sigma} \bar{P}^{\sigma-1} \frac{g(\varphi)}{1 - G(\varphi_0)} M_0 \partial \varphi
\]

\[
+ \sum_{n=1}^{N} \left( \int_{\varphi_n^{w}}^{\varphi_n} p_n(\varphi, 0)^{1-\sigma} \bar{P}^{\sigma-1} \frac{g(\varphi)}{1 - G(\varphi_0)} M_0 \partial \varphi \right)
\]

\[
= \bar{M} \left( \bar{P} \bar{\varphi} \rho \right)^{\sigma-1}
\]

(26)

Finally, we use equations (25) and (26) to solve for the aggregate price index, \( \bar{P} \), and the mass of

---

\(^{53}\)A detailed derivation of this representation of aggregate retail sales is provided in section 2.5 of the online appendix.

\(^{54}\)That is, the aggregate price index is: \( \bar{P} = \left( P_0^{1-\sigma} + \tau_B^{1-\sigma} \right)^{1/(1-\sigma)} \), and the retail price index is: \( P = \left( P_0^{1-\sigma} + \sum_{n=1}^{N} (P_n^{1-\sigma} + P_n^{1-\sigma}) \right)^{1/(1-\sigma)} \); where \( P_0 \) is the CES price index for domestic retail varieties, and \( P_n^w \) and \( P_n \) are, respectively, the CES price indexes for indirect and direct imported varieties from country \( n \).

\(^{55}\)A detailed derivation of this representation of aggregate expenditures is provided in section 2.6 of the online appendix.
varieties, \( \bar{M} \):\(^{56} \)

\[
\bar{P} = (\sigma f)^{\frac{1}{\rho \varphi_0}}, \quad \bar{M} = \frac{\bar{P}^{1-\sigma} - \tau_B^{1-\sigma}}{(\rho \bar{\varphi})^{\sigma-1}}
\]

Note that \( \bar{\varphi} \) is not a function of the mass of varieties, despite the fact that \( M_0, M^w_n, M_n, \) and \( \bar{M} \) appear in the definition of \( \bar{\varphi} \) in equation (24). To see why this is true note that \( (M^w_n + M_n) \) can be written as function of the mass of domestic varieties, \( M_0 \), the cutoff, \( \varphi_0 \), and the parameters of the model. \( M_0 \) can then be factored so that \( \bar{\varphi} \) is a function of the ratio \( M_0/\bar{M} \), which also only depends on \( \varphi_0 \), and the parameters of the model. Therefore, \( \varphi_0 \) is the only endogenous variable that determines \( \bar{\varphi}, \bar{P}, \) and \( \bar{M} \). As discussed in section 2.2, the equilibrium value of \( \varphi_0 \) is determined by the free-entry condition, \( \bar{\pi} = f_e (1 - G(\varphi_0))^{-1} \), and the expression for mean retailer profits in equation (2).

7 Empirical Appendix

7.1 Propensity score matching (PSM) technique

The results derived from OLS and FE specifications provide evidence that direct importing retailers perform significantly better, in terms of sales, than other retailers during exchange rate appreciations. In principle, this result could be driven by either a causal effect of exchange rate appreciations on direct-importing-firm sales (relative to other firms), or by self-selection of high-performing retail firms into importing in response to appreciations. Both of these effects are consistent with the theoretical model derived in section 2. While firm-level fixed-effects control for any time-invariant components of self-selection bias, changes over time at the firm level could lead to self-selection into importing during exchange rate appreciations and, therefore, stand in the way of causal interpretation for results from the OLS and FE regressions.

To identify the casual effect of exchange rate changes on direct-importing-firm performance, we apply a propensity score matching (PSM) technique, taking motivation from recent work by Meinen and Raff (2018) and others. Our approach uses PSM to create matches between a treatment group of direct importing firms and a control group of non-direct-importing retailers that have a similar propensity to import as the control group. We then estimate equation (16) using OLS on our matched treatment and control firms only, with control firms equally weighted as their matched treatment firms.

\(^{56}\)A detailed derivation of the aggregate price index and the mass of varieties is provided in section 2.7 of the online appendix.
The first step in this technique involves estimating import propensity based on observables. We follow Meinen and Raff (2018) and employ the following probit model:

\[ P(1(Importer_{i,t})) = \phi \{X_{i,t-1}\}, \quad (27) \]

where \( \phi(\cdot) \) denotes the normal CDF and \( X_{i,t-1} \) contains a set of firm-level variables, lagged by one year, that are significantly correlated with direct importing. In our application, the vector \( X_{i,t} \) includes the following variables: the logarithm of labour productivity (value-added per employee), the logarithm of number of employees, wage share in total sales, and total sales growth. Labour productivity and employment are included in \( X_{i,t} \) since both are positively associated with firm-level direct importing according to our model and other evidence. Wage share in total sales is included to capture the firm’s cyclical position, and sales growth is included as an additional measure of productivity. Our probit regressions also include industry and year dummies. All variables included in the right-hand side of (27) are also included by Meinen and Raff (2018) in their analysis.\(^{57}\) This exercise produces estimates for propensity scores that vary across firm-year observations in our sample.

To estimate (27), we require data for labour productivity\(_{i,t} \), number of employees\(_{i,t} \), wage share\(_{i,t} \), and sales growth\(_{i,t} \). We define labour productivity\(_{i,t} = \text{value-added}_{i,t}/(\text{number of employees}_{i,t}) \), where number of employees\(_{i,t} = (\text{wages and salaries}_{i,t})/\text{wage}_{i,t} \); wages and salaries\(_{i,t} \) is derived from the income statement of the firm, as reported to tax authorities, and reported in the National Accounts Longitudinal Microdata File (NALMF); wage\(_{i,t} = (\text{total firm payroll}_{i,t})/(\text{average number of employees}_{i,t}) \), where both total firm payroll\(_{i,t} \) and average number of employees\(_{i,t} \) are derived from Payroll Deductions and Remittances data, as reported to tax authorities, and reported in NALMF. We define wage share\(_{i,t} = (\text{wages and salaries}_{i,t})/(\text{total sales}_{i,t}) \). Finally, sales growth\(_{i,t} \) is defined as annual change in total sales\(_{i,t} \). Values of total sales\(_{i,t} \), value-added\(_{i,t} \), wages and salaries\(_{i,t} \), and wage\(_{i,t} \) are deflated using industry-level CPIs. We drop all values that are less than zero and more than five standard deviations above or below the median.

\(^{57}\)Meinen and Raff (2018) also include the logarithm of labour productivity squared. We exclude this variable since it was not found to be statistically significant in the estimation.
to generate probability weights, to be used for equal weighting of treatment and control groups.  

Finally, we estimate regression equation (16) by OLS, with standard errors clustered at the firm level, weighted by our estimated probability weights.

\footnote{We modify propensity scores to have non-overlapping coverage for each year, to ensure that any two observations with the same propensity score fall in a common year. To ensure common support, we delete all observations where propensity scores for the treatment group (importers) fall outside of the estimated range found for the control group (non-importers).}
